The Delta Independent Science Board thanks the many panelists, workshop participants, questionnaire responders, interviewees, and reviewers of report drafts (listed in Appendix B) for their extensive thoughts, insights, and comments.
Executive Summary

The Sacramento-San Joaquin Delta Reform Act of 2009 mandates the balancing of coequal goals for the Delta: providing a reliable water supply for both the Delta and California and protecting, restoring, and enhancing the Delta ecosystem and the Delta as an evolving place. This review by the Delta Independent Science Board (Delta ISB) presents findings and recommendations on the science and practice of estimating water supply reliability with a focus on the Delta.

This report responds to the Delta ISB’s legislative mandate to review the adequacy of science supporting adaptive management for the Delta. Accordingly, the Delta ISB undertook a review of scientific and formal methods to estimate water supply reliability. The review sought perspectives from stakeholders, managers, and experts by formal presentations and questionnaires, a workshop, and interviews. It draws heavily from these forums and the scientific literature.

A reliable water supply for California is defined in the Delta Plan as “better matching the state’s demands for reasonable and beneficial uses of water to the available supply.” Water supply reliability estimation, the subject of this review, is the formal process of quantitatively predicting performance and water delivery from a water supply system. Reliability usually is expressed as a probability of achieving water system performance objectives. The most common performance metric is a probability distribution of water delivery quantity, but a variety of engineering, public health, economic, social, and ecosystem health metrics also are in use. Reliability is commonly estimated for both seasonal operations and various long-term policy and planning horizons.

Formal performance assessments in general improve management and policy discussions and actions, particularly for complex and changing problems involving many managers and stakeholders with diverse interests. The degree to which both State legislated coequal goals under the Delta Reform Act of 2009 are met is challenging to assess. Of these, estimating water supply reliability might be the most amenable to formal quantitative assessment.

A reliable water supply is critical to California's public health, economic prosperity, ecosystem health, and social well-being. Achieving a reliable supply, however, is challenging because of California's diverse landscape and climate, unequally distributed and variable precipitation, complex infrastructure, decentralized institutions, and competing water demands from agriculture, cities, and the environment. In addition, the climate of California is undergoing major long term change.
Water supply reliability estimation has a long history of use in water planning and management in California. It formally originated in civil engineering in the late-19th century to size new reservoirs to supply water with 100% reliability based on historical streamflow records. By the 1980’s, this approach was replaced in California by a more realistic and probabilistic understanding of relationships between variable streamflow, water storage capacity, and water deliveries considering fluctuating water supplies and demands.

Extreme events, such as droughts, test water management systems and require public and political authorities to consider, adapt, and invest in new solutions and approaches. Droughts have always led to improvements in California’s water reliability (Pinter et al. 2019).

The 2020 to 2021 drought has revealed higher water reliabilities for communities and regions that have made effective long-term preparations and investments. The need to improve runoff predictions with a warmer climate, as well as flows and water temperatures for fish is also clear. This experience with drought is another example of how reliability estimation is fundamental for reasoned design of investments and preparations across the wide range of water management events, actions, and purposes.

This review identifies three broad challenges for water supply reliability analyses: environmental concerns, technical and management issues, and modeling and managing uncertainties. Environmental concerns, particularly the desire to maintain aquatic habitat, adds a new type of reliability assessment relative to past efforts. Both water quantity and quality (e.g., salinity and temperature) will determine the ability of species to survive and reproduce. Technical and management issues include increasing the breadth and realism of aspects of water management portfolios (multiple water sources, operations, and demand management) in water supply reliability modeling. Such portfolios include multiple approaches for adaptive decision making. Modeling and managing uncertainties will be necessary to support risk management given the highly uncertain and non-stationary aspects of climate change. Methods include more formal multiple objective analysis, broadening forecast-informed reservoir operations (FIRO) to include multiple reservoirs and support for environmental flow management, adopting new technologies to process and share data and models.

Effective water supply reliability analyses and estimates are fundamental to managing water in California. Unfortunately, water supply reliability analysis is often conducted in non-reproducible ways without sufficient testing, interpretation, and documentation. Further, a lack of a coordinated or systems-level approach to
water supply modeling may unnecessarily narrow the management options being considered. As a result, methods currently in use can make reliability results hard to employ in public and agency deliberations and may be insufficient for managing increasing uncertainty of climate.

Findings and Recommendations

This review led to the following findings and recommendations on the science and practice of water supply reliability estimation. Implementing the recommendations will make reliability estimates more useful for policy and management discussions and decisions.

Findings

Broad Importance of Water Supply Reliability and Estimations

1. Water supply reliability analysis is applied to adaptively manage water supply under the multiple factors of climate change, changing demand, new regulations on environmental flows, and system disruptions due to extreme events.

2. Most major water suppliers (urban and state projects) employ formal reliability analyses for water operations, planning, and policy decision-making in California and the Delta.

3. Meeting ecological goals requires reliable water supplies, but a consensus on methods to quantify water supply reliability to meet these goals is lacking.

4. Reducing risks to human and ecological systems from drought under changing future conditions is a major motivation of current efforts to improve water supply reliability analyses.

Analysis of Water Supply Reliability

5. Unreliability of water supplies has many sources, including drought, natural catastrophes (such as floods, wildfires, and earthquakes), mechanical breakdowns, chemical contamination, changing human behavior and climate, and sub-optimal system management.

6. A portfolio approach that integrates management of both demands and supplies has a long history of effectiveness in California. Urban water systems, particularly in southern California, are international leaders in combining portfolio management and reliability analysis. Agricultural users
are moving in this direction by using new water management approaches. Environmental water systems might benefit from employing portfolio management of supplies and demands for water and habitats.

7. Reliability under a changing climate depends on early and effective preparations by local and regional water agencies. In particular, sea level rise in the Delta (and its effects on encroaching salinity, flooding, and water quality) and increased water temperatures affecting ecosystems will have wide-ranging implications on the reliability of water supplies in California for all water uses.

8. Many approaches have been used in California to estimate water supply reliability. Each approach has advantages and limitations. Methods developed for narrow applications tend to be more rigorous, but are not easily applied to other applications.

9. Probabilistic approaches to water supply reliability capture much of the uncertainty associated with changing conditions and, therefore, support development of balanced water management portfolios. Non-probabilistic scenarios and sensitivity analyses remain useful to explore the stability, economy, and adaptability of water management solutions.

**Reliability Analyses for Management and Policy**

10. Water supply reliability estimates are sensitive to underlying assumptions, but the effects of this uncertainty on management recommendations are rarely made clear and explicit to managers and stakeholders.

11. Water supply reliability analyses could be better integrated into water operation, planning, and policy decision-making to improve and focus deliberations on performance and trade-offs among multiple objectives.

12. State, regional, and local agency expertise in water supply reliability estimation is scarce and often not current with the state of the science and escalating challenges. This staffing problem is likely to worsen as demands on agencies increase and senior staff retire.
**Recommendations**

**Practice**

1. *Most water supply reliability analyses in California should reflect complex portfolio-based water management* to improve cost-effectiveness and equity of regional water management among diverse entities. Portfolio management includes evaluating interacting surface-water and groundwater sources, infrastructure operations, and water demand management in multiple sectors. (Findings 3,4,5,6,9,10)

2. *Performance assessment of water system reliability should be broadened beyond technical reliability to include multiple benefits that support management of public health and other economic, ecological, and social objectives.* (Findings 1,2,3,10)

3. *A common State water accounting system, including better documentation, interpretation, testing, and standardization, should be developed that improves technical quality, comparability, and communication for both technical and non-technical audiences.* The California Department of Water Resources and the State Water Resources Control Board could jointly administer such an accounting system and technical expectations. (Findings 1,2,5,8,9,10,11)

4. *The next generation of state-sponsored water supply system models for reliability estimation should be built, updated, and evaluated by a broad consortium of state and federal agencies and external experts in order to better incorporate regional management needs and apply the best feasible science.* Collaboration and coordination have the potential to reduce the costs of model development, while improving model utility and model coordination across regional operations. Due to the ongoing need for system-specific modeling for some types of decisions, a hierarchical approach to coordinated modeling, which uses coarse, intermediate and detailed system models, may be the best approach to increase model comparability, accelerate model upgrades, and broaden analysis scope. (Findings 5,8,9,10,11)

**Research**

5. *Specific performance metrics and analysis methods for environmental water supply reliability should be developed that will better inform policies that support the Delta’s co-equal goals.* A “functional flows” approach that reflects
reliability of meeting ecosystem and species spatial and temporal water needs would improve ecosystem management. (Findings 1,3,4,6)

6. **Analytic methods that reflect expected climate change effects, combined with uncertainty analysis, should be updated. This would improve long-term planning and policymaking.** Combining scenario-based and probabilistic analyses can quantify uncertainty and identify promising adaptable portfolios of management actions. (Findings 1,4,5,7,9)

7. **Investment in research and education should be increased to improve water supply reliability estimation science and practice.** Some recommended areas of research and funding emphasis include: a) nexus of water quality and water supply reliability, b) modeling of large regional water operations, c) applying uncertainty analysis in planning and policy decisions, and d) education of staff in State agencies to promote more rigorous, advanced, and insightful analyses. (Findings 2,3,4,5,6,9,10,11,12)
1. Introduction

“The present only touches you:
But oh! I backward cast my eye,
On prospects dreary!
And forward, though I cannot see,
I guess and fear!”
To a Mouse, Robert Burns 1785

California’s prosperity, ecosystems, and quality of life depend on water. It is not always worthwhile, however, in financial, environmental, and opportunity cost terms, to eliminate all water scarcity. Thus, the estimation of water supply reliability is often central in balancing water policy and management discussions for the Sacramento-San Joaquin Delta and California. This report examines the science and organization of water supply reliability estimation to help improve these public and management discussions and decisions.

Water supply reliability estimation as discussed here is the formal process of quantitatively predicting performance and water delivery from a water supply system. Reliability usually is expressed as a probability of achieving water system performance objectives. The most common performance metric is a probability distribution of water delivery quantity, but public health, economic, social, and ecosystem health metrics also are used. Reliability is commonly estimated for both seasonal operations and long-term policy and planning horizons.

Water Supply in California

California is semi-arid, with highly variable precipitation. Its Mediterranean climate delivers almost all precipitation from November to March, with much stored seasonally as snow at higher elevations. However, California’s April to October dry season is generally drier and longer than the worse drought ever seen historically in the eastern United States. California’s annual precipitation is also among the country’s most variable, with far more of dry and wet years (Figure 1, Dettinger 2011). In California, water supplies and demands are mismatched in space and time for human uses: about 70 percent of the state’s precipitation falls in the north while water demands are mostly in the south; and the winter precipitation season does not coincide with the summer season of highest water demand. Some unreliability in water supplies is unavoidable given this great hydrologic variability, diverse water demands, and allocated water rights that greatly exceed average water availability (Grantham and Viers 2014).
California has the nation’s most variable annual precipitation. Annual coefficient of variation for precipitation stations in the continental US. (Coefficient of variation = standard deviation/average) (Dettinger 2011)

The location of the Delta makes it the major hub of California’s water system (Lund 2016). Upstream reservoirs and aquifers are managed to shift water availability from winter and spring to summer and fall, and from wet to drier years. These reservoirs and associated conveyance infrastructure support large water diversions upstream of the Delta and alters seasonal inflow patterns to the Delta, from which additional water is diverted for state, federal, and local water projects. In wetter years and seasons, some Delta water diversions are stored in reservoirs and aquifers in the southern Central Valley, Southern California, and the Bay Area.

Local water agencies and water users in these regions and upstream manage both local and imported water sources together with their water uses. These operations are often coordinated with near and distant neighbors, by contracts, water market transactions, and regulations, to better serve economic, public health, and ecological objectives. Shortages of water to local water users can often be addressed by re-managing local and regional water supplies and demands, including infrastructure re-operation, water market transfers or agreements, and reductions in water use by additional conservation and land fallowing.

The Delta and its management are critical to this intricate and dynamic water supply system. Continuous balancing of widespread and diverse water supplies and demands under widely varying conditions is essential. Achieving this balance falls under the State goal of Water Supply Reliability (in the Delta Reform Act of 2009),
which receives intense interest from policymakers, stakeholders, water managers, and researchers alike.

**Overview of Water Supply Reliability Estimation**

Formal water supply reliability estimation originated in civil engineering in the late-19th century, to size new reservoirs to supply water with 100% reliability based on the historical streamflow record (Rippl 1883). This approach estimated the so-called “firm yield” of a stream and reservoir, the maximum annual demand that could be supplied without shortage (Linsley et al. 1992). “Firm yield” approaches were used to design most major water projects during the early and mid-20th century.

This approach has been replaced by a more probabilistic understanding of relationships between variable streamflow, water storage capacity, and water delivery considering fluctuating water supplies and demands (Hazen 1914; Hirsch 1978; Klemes 1987). Probabilistic estimation of reliabilities for major water supplies was introduced in California in the 1970s and became common by the 1980s (DWR 1983; Barnes and Chung 1986; Table 1).

Figure 2 shows the main components and data flow of a typical modern water supply reliability analysis. In practice, modeling requires representation and integration of hydrologic, water demand, infrastructure capacity, component connections and interactions, and management aspects of water supplies, including their variability and uncertainty (see Appendix A for details). Accordingly, variability in reliability estimations is expected.

![Diagram](image)

**Figure 2. Main components of a typical water supply reliability analysis.**
Hydrology of water sources and water demands inform water system management, which in turn determine outputs, measured and interpreted by performance metrics. Water inflows, demands, and operating decisions are modeled for a series of daily, weekly, or monthly time-steps extending over decades of variable hydrologic and operating conditions. These details are discussed in Appendix A.

Modern water supply reliability estimation methods have evolved and broadened considerably since the early emphasis on urban and agricultural supplies. Water supply reliability and its estimation in California face many new challenges:

- Need to further adapt California’s extensive statewide, regional, and local water systems that transport and store water.
  - Development of integrated portfolios of management options - including diverse surface, aquifer, desalinated, and reused water sources, as well as management of water demands, including long-term and drought use reductions;
  - Changes in water storage, conveyance, and treatment infrastructure and technologies, and water management improvements (e.g., reoperation of reservoirs to balance flood management and water supplies; restoration of floodplains and wetlands; groundwater recharge; some capacity improvements).
  - Greater awareness of potential system failures from catastrophic events, such as major earthquakes, floods, contaminant seepage, water-supply terrorism, pandemics, and facility failures;
  - Increasing concerns for drinking water quality and treatment;
  - Complex interactions among the many parts and objectives in California’s water system.

- Water flows have environmental consequences.
  - Recognition of the importance of environmental impacts of water supply and management decisions;
  - Broader and deeper water quality considerations for ecosystems;
  - Environmental regulations that alter urban and agricultural water supplies and demands.

- Increased recognition of social justice concerns.
  - Water availability, safety, and quality for rural drinking water supplies
  - Employment impacts to poor residents of rural and urban areas
  - Costs and affordability for poor urban and rural water users
  - Increased appreciation of implications for Delta communities as an evolving place, including related social justice concerns.

- Climate change.
DRAFT (9/1/2021)

- Ecosystems and hydrologic systems will adapt to new thermal and weather regimes,
- Historical records of unimpaired flows will have diminishing value for estimating water supply availability for both long-term planning and seasonal operations
- The ability of the Delta to supply water of suitable quality for urban and agricultural water diversions will be diminished.

- Regional and global changes affect water demands.
  - Factors outside of the province of water managers often affect water system demands and performance, including changes in societal and environmental attitudes, behavior, land use, population, migration, technology, law, and crop and energy prices.

Water supply reliability has not traditionally incorporated all these factors, so adding them into estimates brings new technical challenges. As an example, water quality, timing, and spatial distribution of flows are important to species in ecosystems, but specific requirements are highly uncertain. Modifying design needs to address climate changes and future human adaptations further compounds uncertainties. Thus, the reliability of long-term water supply estimates involves many unknowns.

Another important consideration is surprises. Surprises are inevitable (Box 1) and can be missed in water supply reliability estimation. Decision makers need to be prepared to consider a wide range of expected and novel extreme events using both probabilistic and robust sensitivity analyses (e.g., Marchau et al. 2019).
Box 1. The challenges of high-impact, low probability (black swan) events

The novel coronavirus (COVID-19) pandemic illustrates a major challenge for uncertainty methods generally. How can system analysts anticipate and treat very low probability events with major impacts that are difficult to identify and characterize in advance? Their omission in engineering design is often excused by their small probability, but they are real, may strike off guard, detrimental, pervasive, and overwhelm human and natural systems.

Rare and often poorly characterized (or unknown) high impact events fall into two major categories. The first category consists of imaginable events. These are based on historic precedent or a causal understanding for their anticipation. The second category consists of events not imagined by most planners, engineers, experts, leaders, or the public due to a lack of precedents in human history or inadequate understanding for developing meaningful scenarios. Events in the former category are sometimes developed to test project robustness or resiliency. Ironically, such tests are often called worst-case scenarios, although they reflect only imaginable dire circumstances (Brown et al 2012).

It is not difficult to imagine events that could significantly degrade water supply reliability by damaging larger water projects and systems in Delta. These might include: climate changes, “megadroughts,” sea level rise, failures from earthquakes and flooding, volcanic ash deposition, water contamination, increased ecological demand, political upheaval, and terrorism. Once recognized, challenges arise in characterizing these events. The first and major challenge is estimating their frequency needed to calculate risk. This is especially true for events known primarily from geologic and historical records. Second, their magnitude may be difficult to assess. For example, coring in today’s Delta reveals volcanic ash layers that indicate airborne debris from large Cascadian volcanic eruptions once choked the modern Delta region in the Pleistocene. Although many details are unknown, a reoccurrence would be a hazard to turbine pumps, human health, water quality, agriculture, and ecosystems in the present day (Maier, et al. 2015). Third, some scenarios are based on nonstationary processes. For example, a recent investigation used dendrochronology in the American West to identify megadroughts that occurred on the average approximately every 240 years (Williams et al., 2020). While this information is useful to estimate their frequency, climate change may alter the frequency of megadroughts. Indeed, the authors concluded that anthropogenic warming strengthened the 2000 to 2018 megadrought. Finally, human and management responses to extreme events are often highly uncertain, particularly in decentrally-managed systems, where some solutions require Herculean agreements while other solutions are easier to implement.

Unimagined surprise events, the second category, are the unknown unknowns popularized by former U.S. Secretary of Defense, Donald Rumsfeld. In Nassim Talib’s The Black Swan (2007), these are unpredictable events with massive consequences that can be rationalized only retroactively. Although unimagined events are inherently difficult to accommodate in engineering design, their existence may expose a system vulnerability caused by ignorance or human limitations. Humans tend to focus on things they know and disregard things they do not know. Acceptance of ignorance or limitations of thinking capacity and controllability of events may encourage increased resiliency and preparation for adaptation in designs. A ‘perfect storm’ of component failures might wreak havoc even in supposedly well-engineered systems, as happened in the 2011 Tohoku, Japan, earthquake and tsunami.

Both the COVID-19 pandemic and low-probability, high-impact, events in general beget humility. Operational success of projects is not fully guaranteed regardless of how well a probabilistic method for design is formulated. History is replete with catastrophic events, imagined and unimagined, that with advantage of hindsight fell in the tails of prior probability distributions. History also shows numerous cases where well organized, adaptable, and well-prepared systems responding effectively, despite damages and losses, to large unpleasant surprises.

Surprises happen in water management and should be considered and be prepared for in water supply reliability estimation and analyses.
This review responds to the Delta ISB’s legislative mandate to review the adequacy of science supporting adaptive management for the Delta. Accordingly, the Delta ISB undertook this review of scientific and formal methods to estimate water supply reliability as it pertains to the Delta. The review sought the perspective of stakeholders and managers by formal presentations and questionnaires, a workshop, and interviews (Appendix B). It presents scientific and technical aspects of estimating water supply reliability to support California’s diverse water management system for urban, agricultural, and environmental purposes with an evolving Delta and context. It draws from these forums and the literature on water supply reliability estimation.

Following this introduction, Section 2 of this report reviews sources of water supply unreliability and provides a partial inventory of water supply reliability estimation applications. Section 3 summarizes commonly employed metrics to assess water supply reliability. Section 4 reviews scientific challenges for water supply reliability estimation, with particular emphasis on climate change, portfolio management, water quality and quantity, environmental water supply reliability, uncertainty analysis, and analysis for multiple-objectives and conflict management. Section 5 presents methods and considerations to improve quality control of reliability estimation and its effectiveness. Section 6 focuses on water supply reliability in decision-making. Finally, Section 7 makes some overall concluding remarks, with findings and recommendations already provided in the executive summary. Three appendices present some important technical issues for water supply reliability modeling and analyses, summarize insights from the pre-workshop questionnaire and post-workshop interviews, and present acronym definitions.
2. Water supply reliability analysis in California

Many human and environmental water users in California draw their water directly from the Delta (averaging about 5 million acre-ft/year). Still greater volumes of water are drawn indirectly from the Delta by upstream surface and groundwater users. The Delta is the major hub of the CVP and SWP, backbones of California’s water supply network. Thus, the Delta is central to the extensive and often overlapping integrated portfolios of water supplies, demands, and infrastructure managed by hundreds of agencies and millions of users. Today, water in and from the Delta is becoming more important and increasingly threatened by droughts, floods, climate change, groundwater depletion, population growth, vulnerable infrastructure, and deteriorating ecosystem health (Lund 2016; Schwartz et al. 2020).

Regulatory requirements add to the water management challenge. The Federal 1992 Central Valley Project Improvement Act requires that the CVP dedicate part of its water allocation for fish and wildlife. California’s Sustainable Groundwater Management Act will end the groundwater overdraft, but increase water demands on the Delta and other sources by about 2 million acre-feet/year (maf/yr), although most of this new demand seems unlikely to be fulfilled (Dogan et al. 2019). New proposals for Delta and tributary environmental flows or voluntary agreements could further modify water operations and Delta water availability for diversions.

Three successive droughts with accompanying water delivery cutbacks, declining fish populations, increased attention to levee fragility (Roe et al. 2016), and increased litigation and regulations, led California’s legislature to pass the Sacramento-San Joaquin Delta Reform Act in 2009 (Frank 2010). The Act declares two coequal goals for the Delta: (1) provide a more reliable water supply for California and (2) protect, restore, and enhance the Delta ecosystem, while protecting and enhancing the unique cultural, recreational, natural resources and agricultural values of the Delta as an evolving place. Reliable water supplies are critical to meet the coequal goals, and to successfully manage California’s water resources.

Droughts highlight diverse water supply reliability concerns in California (Durand et al. 2020).

Causes of Water Supply Unreliability

Estimations of water supply reliability tend to emphasize reductions of inflow, caused by drought and changes in regional climate and water demands. However,
water shortages may also arise locally from wildfires (Paradise, California), floods (disabling intakes and water treatment plants), internal management and operational failures (Flint, Michigan), upstream water quality declines, harmful algal blooms (Toledo, Ohio in 2014), contamination, black-swan events (Box 1; Chan and Ho 2019; Howe et al. 2018), mechanical and electrical infrastructure failure, earthquakes and complex environmental and water rights regulations (Grantham et al. 2014, 2018).

Delta water source reliability is unusual. Because the Delta is connected to the ocean and is mostly at or below sea level, the Delta always has water available. However, the quality of this water is unreliable at locations in the Delta when Delta inflows are insufficient and exports are too great. These water quality effects can limit water uses from western Delta diversion (such as the City of Antioch) and progressively affect additional in-Delta and Delta export diversions when net outflows diminish enough to allow ocean salts to intrude further into the Delta with tidal mixing (Young 1929; Fleenor et al 2008; Jayasundara et al. 2020; Medellín-Azuara et al. 2014).

An ongoing example of infrastructure failure is the reduced capacity of the CVP’s Friant-Kern Canal caused by over-pumping of groundwater and land subsidence, lowering reaches of the canal and reducing its capacity (Borchers et al. 2014). Water shortages also may occur from increased demand, new environmental and water quality regulations, and failure of agreements or institutional rules (such as failed water trades). It is rarely possible to identify and anticipate all possible failure mechanisms, and practically impossible to accurately represent all failure mechanisms explicitly in models. This is particularly true for California’s complex water systems. Complexity often brings flexibility and robustness, but sometimes can introduce new sources of unreliability.

All estimates of reliability are fallible, so additional stress-testing analyses for improbable, but plausible, events can explore the robustness of designs and adaptations (Dittrich et al. 2016; Groves et al. 2019). Even imperfect water supply reliability analyses can help organize and focus discussions and planning, and inform reasoned decisions on California’s difficult water and environmental problems.

A Selective Inventory of Reliability Estimation Efforts

California’s largest water supply systems routinely estimate water supply reliability for policy, planning, and operational decision-making (Table 1 and Jackson 2006).
Water supply unreliability does not necessarily translate directly into water shortages or large economic or environmental losses. Water supply reliability analyses fall into two categories: a) examinations of source delivery reliability (DR/delivery reliability in Table 1) and b) examinations of integrated system reliabilities (ISR/integrated system reliability in Table 1). Water source reliability estimates are more limited, focusing only on the probability distribution of water available for delivery from a source, such as the SWP. Water system performance reliability estimates combine reliabilities of various water sources and system components, as well as the significance of any resulting economic, human, or environmental losses, often mitigated by infrastructure operation and demand management activities, such as that done by the Metropolitan Water District of California (MWDSC). Every integrated system reliability study includes estimates of source reliability, as well as supply and demand adaptability to water availability conditions, which reduce water shortages and impacts.

SWP and CVP source reliability studies are often employed within broader regional or local system reliability studies such as MWDSC (2015), which include a wider portfolio of supplies and demand management activities to reduce overall losses from traditional water supplies. Some examples are identified in Table 1.

Note: DR=delivery reliability, examines only the reliabilities of water delivered; ISR = integrated system reliability, examines the reliabilities of a broader management portfolio, including sources, infrastructure, agreements, and demands.

California's Department of Water Resources has separate organizational units that estimate water supply reliability for seasonal State Water Project operations, State Water Project Planning (DWR 2017, 2020), the California Water Plan (DWR 1983, and later plans), climate change (Ray et al. 2020; Schwarz et al. 2018, 2020), and Sustainable Groundwater Management implementation (DWR 2018). The California Department of Water Resources in conjunction with the United States Bureau of Reclamation has developed sophisticated software called the Water Resources Integrated Modeling System (WRIMS), which support their CALSIM and CalLite models (Barnes and Chung 1986; Draper et al. 2004; Islam et al. 2011). This modeling usually includes representations of salinity in the Delta, modeled using hydrodynamic (DSM2) or faster artificial neural network models (Jayasundara et al. 2020).

The California Department of Water Resources also has a capability to do more integrated system performance reliability assessments for SWP service areas, using CALSIM or WEAP models for water source reliability, and economic models of local agricultural and urban water source and demand management.

The State Water Resources Control Board independently estimates water supply reliability for water rights in its Water Rights Division (water balance analyses, SWRCB 2020) and environmental flow regulations (SacWAM, SEI 2019). Water supply reliability estimates for Federal water projects in California are mostly performed by the U.S. Bureau of Reclamation in its operations and planning units (USBR and USDOI). Modeling for planning in the last 20 years or so has historically used versions of CALSIM II, but USBR's CalLite is implemented in another simulation package. CALSIM 3.0 is a newer model expected to replace CALSIM II (DWR and USBR 2017). Some regional modeling studies use WEAP software (Mehta et al. 2013; Joyce et al. 2011).

Local and regional water utilities in California individually estimate water supply reliability in various ways for planning, policy, and operational purposes. (e.g.,
Southern California’s urban water systems have tended to be leaders in portfolio management and more integrated system analyses. Environmental organizations also have done water supply reliability assessments for policy and planning (The Nature Conservancy, Restore Hetch Hetchy, Environmental Defense Fund). Many water supply reliability studies are done by the sponsoring organizations themselves, and many are done partly or wholly by consultants, with several firms specializing in such studies (e.g., MBK, Jacobs, Stantec, HDR, Woodard and Curran, GEI) (MBK Engineers and Steiner 2014; Lefkoff and Kendall 1996). Cost, data availability, technical capability/staffing are barriers for smaller water suppliers. There are many small water suppliers, and they usually are more vulnerable to unreliability, as seen during droughts.

Academic studies have advanced methodology and insights for water supply reliability estimation in case studies of several water systems in California. These have examined:

- Reliability and operations for CVP and SWP water deliveries (Becker et al. 1976; Marino and Loaiciga 1985; Roche 2020)
- Water markets, conjunctive use, and integrated management (Jenkins and Lund 2000, 2004; Medellin et al 2008; Lund et al. 1998; Tanaka et al. 2006, 2011; Dogan et al. 2018; Arnold 2021)
- Regional water portfolio reliability (Porse et al. 2017, 2018; Mann et al. 2017; Groves et al 2014)
- Sensitivity to hydrologic foresight and reservoir operations (Arnold 2021)
- Aquifer recharge with flood waters (Kocis and Dahlke 2017; Escriva-Bou and Hanak 2018)
- Aquifer recovery reliability under Sustainable Groundwater Management Act (Escriva-Bou et al. 2020)
- Distribution system reliability (Gheisi et al. 2016)
- Reliability of evapotranspiration estimates (Medellin et al. 2018)
- Institutional reliability in conflict resolution (Al-Juaidi & Hegazy 2017)

Reliability studies are common for major water supply systems globally as well. Globally, water supply reliability estimates increasingly take one of many variants on an integrated system approach. Examples include planning and operation analyses for New York City (Porter et al. 2015; NASEM 2018, 2020), South Florida (SFWMD 2020), Las Vegas (Ahmed 2016), Sidney (Australia) (Kidson et al. 2013), and
London (Matrosov et al 2013, 2015; Morley and Savić 2020), northeastern Colorado (Michelsen and Young 1993), other systems (Raucher and Raucher 2015).

3. Metrics of Water Supply Reliability and Their Use

“When you get rid of what you don’t want, you do not necessarily get what you do want and you may get something you want a lot less.” Russell Ackoff

Many metrics of water supply reliability are in use. Most metrics have been developed for urban and agricultural water systems. However, there has been a surge in efforts to develop indicators of water supply reliability for environmental purposes. Well-developed and employed metrics help analysts, managers, and policy-makers to understand and explore water systems, solutions, and their performance.

Metrics for complex systems always lose some (sometimes important) details. It is tempting to summarize indices to an extreme, such as developing indices of indices. The best metrics improve management and understanding by focusing voluminous modeled or observed results into a few informative statistics or depictions.

The definition and use of a metric itself can be complex and controversial. In essence, good metrics provide management or scientific insights by summarizing performance or conditions for the decision-maker or analyst. Poor metrics and poor use of metrics can mislead or distract management and scientific discussions from more important aspects of problems or solutions.

Assessment of metrics also rests on the accuracy of the data, models, and methods used to calculate them. Because all metrics have uncertainty, analysts should explore and quantify major uncertainties. Decision-making deliberations should keep these uncertainties in mind.

**Common Metrics of Water Supply Reliability**

Dozens of metrics have been proposed to assess water supply reliability for urban, agricultural, navigation, and hydropower performance (Rippl 1883; Riggs and Hardison 1973; USACE 1975; Hirsch 1978; Klemes 1987; Basson et al. 1994). Table 2 summarizes some common metrics. Many additional metrics exist for evaluating water distribution system performance (USEPA 2015). Each metric provides insights into different aspects of desirable water supply performance, but no single metric provides a complete picture of water supply reliability.
This table and discussion distinguish between technical and fundamental performance metrics. Ecologic or environmental performance objectives are relatively new and are discussed in a later section.

Technical Metrics

Technical metrics typically summarize current or forecast water deliveries or storage conditions (Table 2). These metrics are convenient for system operators to assess likely performance, usually in the context of their water management experience, and so help with operational or system design decisions. Some common metrics are:

*Average delivery capability* is the mean annual or seasonal water volume available for delivery from a water supply system. Although this calculation is straightforward, it is rarely used in practice because variability in delivery capability is crucial for the success of a water supply system, particularly in Mediterranean climates like that in California.

*Design drought delivery* is common for water systems designed to accommodate specific design droughts. California’s larger urban water suppliers, with more than 3,300 customers, are required to produce Urban Water Management Plans (UWMPs) every 5 years, which describe “the reliability of the water supply and vulnerability to seasonal or climatic shortage” for an average year, a single dry year, and multiple dry years (CWC 10631 (c)(1)). These UWMPs also must specify actions planned to accommodate up to a 50 percent reduction in water supply (CWC 10632 (a)(1)).

*Firm yield* (sometimes misleadingly called “safe yield”) is the amount of water that can be supplied without any shortage for a repeat of the historical hydrologic record (using critical drought of record as a design drought). It is a classical conservative water supply reliability metric (Rippl 1883; Linsley et al. 1992). Historically, firm yield was the primary metric used for the design and assessment of United States reservoir systems, including major projects in California. The metric remains useful to indicate if water shortages are likely to be a problem. When a system’s water use exceeds its “firm yield,” drought concerns rise and more elaborate performance metrics and system contingencies and plans are needed, as is common in drier regions with great annual hydrologic variability, such as California.

*Probability of shortage* is the likelihood that a particular water right or use will experience a shortage in a planning or seasonal timeframe. Figure 3 shows the results of a water rights analysis using historical flow estimates, indicating the probabilities of each of roughly 800 San Joaquin Basin surface water rights being curtailed (Walker 2017). The probability of being curtailed varies greatly with the type and priority of water right and its location in the basin. Upstream tributary users, even those with high priority, are more likely to be curtailed for lack of local
water availability, whereas downstream users, even those with lower priority, tend to have more reliable supplies because they can be supplied from several tributaries.

![Probability of Shortage by Priority - July](image)

**Figure 3. San Joaquin Basin July Water Right Shortage Probabilities** (from Walker 2017)

*Delivery-reliability distributions* (Hazen 1914) arose from a deeper understanding of reliability, particularly the realization that a range of water volumes can be provided with different probabilities or likelihoods. Instead of being a single number (e.g., *firm yield*), water supply delivery-reliabilities are calculated and presented as a probability distribution. Water supply deliver-reliability distributions are common for most of California's major water systems today (DWR 1983, 1987). Management targets might be expressed as average probability performance, such as some probability of failure to meet a delivery target (such as a 5 percent annual chance of exceeding a 20 percent shortage). However, the entire distribution of delivery-reliability also can be used for further analysis for management and evaluation of broader and more complex portfolios of actions.

Figure 4 shows estimated delivery-reliability distributions for the SWP, comparing 2015 and 2017 analysis results (DWR 2017). Various depictions of delivery-reliability include cumulative and density distributions of deliveries or water delivery shortages (Figures Cover, 4, and 5). (Table A water is a contractual basis for apportioning water supply and costs to SWP contractors.)
Figure 4. Estimated likelihood of SWP Table A Water Deliveries by increments of 500 taf (excluding Butte County and Yuba City). The dashed box shows there is a 77 percent chance of SWP Table A water delivery of more than 2,000 thousand acre-feet (taf) in 2017 (from DWR 2017 Delivery Capability Report - DCR; modified for accessibility)

*Position analyses* are a common variant of delivery reliability plots (Hirsch 1978; FitzHugh 2016), which plot and compare operational results from a set of equally-likely input or hydrologic scenarios, e.g., Figure 5. Such plots and analyses are common for seasonal or real-time operation delivery and performance reliability.

Figure 5. Example of a Position Analysis display of water storage trace results for Shasta Reservoir in 2011 (wet year) and 2015 (dry year). (FitzHugh 2016)

*Engineering performance indices* (Table 2) are a subset of technical metrics that focus on different aspects of water supply reliability performance (Hashimoto, et al. 1982a, b; Shamir and Howard 1981; Vogel and Castellarin 2017; Vogel et al. 2007;
Homa et al. 2005; Kuria and Vogel 2015). Management targets might be expressed as average performance or some exceedence probability of an index target (such as no more than a 5 percent annual chance of exceeding a 20 percent shortage). Examples of engineering performance indices include:

- **Reliability** - Percentage of years or time that a water supply system can or cannot meet a target delivery (or other target metric such as storage balance, groundwater elevation, etc.).
- **Vulnerability** - The magnitude of shortage that occurs when a system cannot supply its delivery target, often the average or extreme shortage.
- **Resilience** - The amount of time likely needed for a system to return to supplying a delivery target, after it has failed. A resilient system tends to quickly return to a functioning one after a failure. Recent diverse usage of “resilience” has made this technical metric less useful.
- **Robustness** - The amount of disturbance needed for a system to fail to supply a target delivery (Hashimoto et al. 1982b). More recently, this approach has broadened to take advantage of the surge in computational capabilities, to identify the range of conditions or disturbances for which target deliveries are attained based on hundreds or thousands of future scenarios. Sometimes statistics are calculated on the percentage of scenarios that fail to achieve different levels of performance (Herman et al. 2016, 2020; Erfani et al. 2018).

**Fundamental Performance Metrics**

A variety of performance metrics reflect the fundamental societal objectives affected by water management and supply reliability.

*Public health indicators* can be specific in terms of days of illness, deaths, average annual years-of-life lost, life expectancy, or other terms. However, public health indicators are usually less direct and reflect concentrations or exceedances of standards for water quality constituents or inability to provide minimal water quantities needed for human health.

*Economic indicators* recognize that not all reliability failures are equally undesirable. Some failures are more economically damaging than others. As water economists may note, “There is rarely a shortage of water, but often a shortage of cheap water.” Economic loss or benefit functions often are employed, or a subsidiary set of economic impact and adaptation models (Howe and Smith 1994; Jenkins et al. 2003; Howitt et al. 2012). Economic indicators can be summarized rigorously as the expected value of net benefits, balancing most of the above considerations in economic terms.
Social indicators for the health, prosperity, and well-being of social groups are sometimes used to characterize effects of decisions and assess equity in the distribution of benefits and risks (USEPA 2021; Teodoro and Saywitz 2020). Environmental justice and social vulnerability indicators can be used to assess equity concerns among socio-demographic groups or places. Social objectives for water management also may be procedural, such as according with principles for the rule of law, property rights, and democratic governance.

Environmental indicators represent the environmental and ecological impacts of system performance and reliability. This newer area of water supply reliability metrics is discussed in the next section.

**Metrics for Environmental Water Supply Reliability**

Performance metrics for environmental objectives continue to evolve to reflect new information and understanding of species and ecosystem demands. Quantitative characterization for environmental and ecological performance is new to water planning and management and has less history and methodological development, with uncertainties on the ecosystem protection effectiveness from particular flow regimes. Quantitative characterization is hindered by the many factors affecting many local ecosystems and species, including a wide range of habitats and water qualities affected by seasonal and inter-annual water operations (Bellido-Leiva et al. 2021). Further, requirements of different species can conflict.

Many metrics of traditional (urban, agricultural, etc.) water supply performance have been applied to environmental water supply performance. The frequency and reliability of a system’s ability to deliver instream or wetland flows or water levels are commonly used to represent whether systems are experience characteristic and supportive hydrologic conditions (Singh 2015; Grantham et al. 2014).

Although still early in development, several approaches are available to represent ecosystem/environmental objectives in water supply reliability analyses (Arthington 2012; Yarnell et al 2015; Williams et al 2019). Environmental water objectives usually are represented as constraints on system operations, implying that minimal environmental targets are met first, with remaining water available for non-environmental purposes. Common approaches (which can overlap) are introduced below, and summarized in Table 3.
**Table 3. Some Metrics of Environmental Water Supply Reliability**

<table>
<thead>
<tr>
<th>Metric</th>
<th>Description</th>

<tr>
<td>Ecosystem species and population indicators</td>
<td>Population indicators, usually from integrating population dynamics models with habitat and flow models.</td>
</tr>
</tbody>
</table>

*Simple flow targets* are common as constraints on water supply operations. While preventing complete drying of streams, minimum flows are often insufficient to achieve broader ecological objectives.

*Natural flow regime standards* usually set flow standards using a historical pre-development flow regime as the basis for environmental flows, allowing some diversions from these historical flows. The idea is to create an environmentally effective flow regime by setting the percentage of natural flow to remain instream for desirable species (usually native fish, trees, etc.) adapted to the natural variability in flows (Poff 2017). This approach is simple to understand and implement, but faces many challenges. Historical goals are more difficult, and perhaps impossible, to achieve due to extreme alterations of the physical landscape (e.g., levees, wetland and floodplain development, and channel hardening), composition of species in the local ecosystem, and climate change. Perhaps the most successful example of this approach is the ELOHA (Ecological Limits of Hydrologic Alteration), because its final results ultimately depend on stakeholder inputs (Poff 2010).

*Composite habitat suitability objectives* recognize the importance of interactions between flow and habitat in supporting species and ecosystems, a variety of interacting habitat and hydrologic models have been developed and applied to set composite habitat objectives for flow and habitat management (Williams et al. 2019). These often are developed for specialized stream, riparian, wetland, or floodplain habitats supporting one of more desired species (Whipple 2018; Williams et al. 2019). Implementing these approaches can be computationally complex and data-intensive, and may not be particularly successful when they estimate only one
component (habitat) of the ecological needs of species. They also often cannot incorporate the benefits of flow variability across seasons (Williams et al. 2019; Whipple and Viers 2019).

*Environmental Functional Flow targets* can be expressed as a set of seasonally varying instream flow targets that represent a variety of ecological functions. These can include minimum instream flows, flow or flow rate change targets to support specific ecological functions (spawning or rearing habitats, fish passage, migration cueing, etc. for specific species or ecosystems), allowable streamflow alterations from unimpaired flow, or allowable water quality conditions (temperature, dissolved oxygen, etc.) (King and Louw 1998; Yarnell et al. 2015; CEFF.ucdavis.edu), as shown in Figure 6. Recent functional environmental flow efforts incorporate landscape changes and modification efforts in flow-setting analyses. Functionally-developed, seasonally-varying environmental flow targets have succeeded in improving ecosystem conditions (Kiernan et al. 2012).

**Figure 6. Functional flow components for California depicted on a representative hydrograph.** Blue line represents median (50th percentile) daily discharge. Gray shading represents 90th to 10th percentiles of daily discharge over the period of record (CEFWG 2020).

*Ecosystem species and population indicators* use estimates of species population or biomass dynamics to explicitly represent ecological objectives of flow and habitat management. This is similar to using economic benefit estimates to more directly represent objectives for societal prosperity. These approaches also explicitly represent life-cycle continuity and population dynamics of species, such as found in
Individual Based Models (Cardwell, et al. 1996; Williams et al. 2019; Adams et al. 2017; Bellido-Leiva et al. 2021). Using more direct population estimates as metrics is less common and more difficult for representing ecosystem objectives, but could be combined with a functional environmental flows approach to quantify the ecological functionality of particular seasonal flows.

Representations of environmental flows or their performance may require very short modeling time steps (15-minutes or hourly) when rapid flow or ecological processes need to be captured. For planning purposes, time increments simplified to daily, weekly, or monthly flow requirements often are deemed sufficient to provide water for finer-scale ecological operations. Environmental flow reliability then can be estimated as probability distributions of the likelihood of desired flow, habitat, or population conditions. Given the approximate, uncertain, and complex relationships between desired environmental objectives and actual ecosystem conditions, there is great uncertainty in the actual ecosystem outcomes from implementation. This imposes a need for adaptive management and suitable field-testing and improvements of models used for environmental flows (Dietze 2017).

4. Challenges for Water Supply Reliability Estimation

The workshop, questionnaire, forums, and interviews conducted for this review highlighted several common scientific challenges in water supply reliability estimation (Appendix C). The topics that received the most attention in the three forums include: planning and management of multiple sources of water supply; water quality; environmental adaptive management, environmental water supply performance metrics (discussed above); impacts from climate change on water supply; and methods to address multiple objectives and conflicts in water planning and operation.

The three forums confirmed that water supply reliability estimation is an active field that continues to evolve. Three ways in which modeling is evolving are that 1) multiple sources of water supply are used, 2) various forms of integrated infrastructure operations and demand management are increasingly incorporated; and 3) supporting ecosystems and water quality are now important societal objectives. Other concerns that are changing reliability estimation methods are uncertainties in how hydrology and water demands will change with future climate conditions, how effective global society will be in mitigating climate change, and how water management systems will adapt to new and changing conditions (Milly et al. 2008). A final concern is that while multi-objective planning and conflict
resolution methods have increased in sophistication, their applications remain limited and have rarely been successfully embedded in actual decision-making.

This section summarizes these concerns in terms of three broad challenges for water supply reliability modeling and analyses: environmental concerns, technical and management advances, and modeling and managing uncertainties.

**Environmental Concerns**

**Climate Change**

“Another area that remains to be addressed is the management response to long-term climate change.” Lettenmaier and Sheer, 1991

Climate change was the most frequently cited concern affecting future water supply reliability estimates in the questionnaire distributed before the review workshop (Appendix C). Seven of 17 respondents to question 4 indicated that climate change uncertainty is a major factor limiting conventional reliability estimation for long-term management and decision-making.

**California’s Fourth Climate Change Assessment** (2018) and a recent Delta vulnerability study (Schwartz et al. 2020) specifically address impacts on water supply. Temperatures are forecasted to increase by 3.1 degrees to 4.9 degrees C (5.6 degrees to 8.8 degrees F) by 2100, and sea levels are forecasted to rise by 50 cm (~20 in) by 2050. Higher temperatures could increase both agricultural and urban water demands, and challenge water temperature management for cold-water species, such as salmon. Higher sea levels pose a threat to Delta levee stability and managing the salt/freshwater interface in the Delta during low river flows. In addition, changes in weather dynamics are expected to increase the severity of both floods and droughts, even though average annual runoff might change little. Atmospheric rivers, which currently deliver 25 to 50 percent of California's annual precipitation, are forecasted to decrease in number by 10 percent, but become longer and wider because the warmer atmosphere can carry more moisture. These changes coupled with a forecasted shift by 2050 in seasonal spring runoff from the winter snowpack to two-thirds of historical levels (and one-third by 2100) are prompting water managers to make water supply forecasts with different and nonstationary climates.

Most current modeling for water supply reliability estimation with climate change is based on climate scenarios. Uncertainty of future carbon dioxide emissions, the main driver of climate change, hinders conventional probabilistic estimates for decision making, along with a number of other sources of uncertainty (Box 2). The USBR (2016) investigation on change and variability in total Delta exports for
multiple climate scenarios is one example. Basically, a sensitivity study by the USBR indicates that climate change will likely reduce Delta exports. Another recent study found likely reductions in SWP exports as well over a wide range of plausible climate changes (Ray, et al. 2020).

The severity of droughts in future climate regimes is being incorporated into some reliability assessments. East Bay Municipal Utility District, for its assessments of future droughts, has relied on the historical record of droughts and then postulated with hypothetical increases in drought duration. Schwarz et al. (2018) conducted a simulation-based assessment of drought impacts on Sacramento and San Joaquin River flows in the Central Valley. They relied on a 1,100-year (reconstructed from a dendrochronology record) to analyze vulnerability to low frequency natural climate variability in concert with forecasted climate change. Their results indicate almost every category of supply system technical performance is likely to decline (e.g., supply, storage, Delta outflow).

Reductions in major Delta water exports have been predicted in essentially every major study of climate change impacts on California water management. These studies use a wide range of scenarios, models, methods, and assumptions (Gleick 1987, 1989; Lettenmaier et al. 1988; Lettenmaier and Gan 1990; Lettenmaier and Sheer 1991; Tanaka et al. 2006; Vicuna and Dracup 2007; Ray et al. 2020; USBR 2016; Schwartz et al. 2018, 2020; Dogan et al. 2018, 2019; Medellin et al. 2008; Connell-Buck et al. 2011). Agency studies have paid less attention to system adaptation and optimization, particularly for California’s diverse portfolio of water management options and activities.

Basic methods for climate change analysis and implications for management in California began more than 30 years ago (Gleick 1987, 1989; Lettenmaier et al. 1988; Lettenmaier and Gan 1990; Lettenmaier and Sheer 1991). The main impacts that were identified have not changed fundamentally, although the analyses are becoming more extensive and sophisticated (Herman et al. 2020; Schwartz et al 2018; Lettenmaier and Lund 2020). One limitation to most studies of climate change impact is that they examine effects of non-stationary hydrology with stationary water management policies in a system that must be managed adaptively. Water management might continue to be the most important non-stationary aspect of water supply reliability, as it has been for over 150 years in California. Analysis to address management dynamically over time with uncertain future climate and other conditions has only recently been formally considered (Herman et al. 2020).
The future climate will differ from the current one. Precipitation, evapotranspiration, water quality and timing of river discharge (Dettinger et al. 2015) and sea levels will all change. The actual future climate, however, will depend on how global society addresses greenhouse gases. The challenge is further compounded by how global climate modelers downscale their predictions to California and the Delta. Thus, the reliability of long-term water supply estimates as climate changes includes some almost unknowable unknowns, as it always has.

**Science for Climate Change in Water Supply Reliability Estimation**

Climate change will require changes in water system operations, regulations infrastructure, demands, and public policies. More integrative modeling of management and water supply reliability that includes climate change will be important for identifying more promising policies and infrastructure.

Substantial management and policy insights can be gained from analysis of single future scenarios (Tanaka et al 2006; Dogan et al. 2019). Examination of multiple climate scenarios, however, can improve estimates of uncertainties and identify promising and robust actions. Alternatively, Bayesian approaches can more rigorously account for the relative likelihood of different scenarios, and how scenario likelihoods will change with time and experience (Fletcher et al. 2019; Hui et al. 2018; Herman et al. 2020). Stress-testing management alternatives with diverse extreme scenarios also provides a prudent form of evaluation (Marchau et al. 2019).

California is unlikely to operate in a new climate with old rules and a narrow range of uncoordinated actions, as assumed in most climate change studies in California. Research will need to focus more on portfolio adaptation than on mitigation, impacts, and scenarios as climate change impacts develop.

**Ecological and Environmental Water Supply**

Balancing ecological and human water uses to meet the State’s coequal goals of the 2009 Delta Reform Act continues to challenge Delta management. No single optimal solution exists for this problem (Alexander et al. 2018). Multiple-objective optimization methods can help identify alternatives that maximize benefits or minimize losses across diverse stakeholders.

When such methods include broad and diverse engagement of affected communities, they can improve both fairness and allocation of resources. Operating favorable flow regimes will be challenging in a constantly changing backdrop of new biological opinions, engineered systems, public perception, and state and federal priorities and regulations.
Science for Improving Environmental Water Supply Reliability

Flow management tools to achieve favorable flow regimes for ecological (for multiple species and ecosystems) and consumptive uses need to be developed. Current methods are fairly crude and focuses on total flow. Guidelines are needed for ecological flows that consider timing and water quality.

More mechanistic fish population and health models based on habitat and flow conditions over seasonal life stages show some promise here, and should be actively extended (Delta ISB 2015). These should provide more solid means to estimate or forecast species and ecosystem performance from water and habitat operations and investments.

“Reconciliation” approaches to ecosystem management seek to greatly expand habitat for native species living outside of protected areas by modifying human land and water use in coordinated ways to accommodate the most important benefits to each interest. Such approaches should be considered for balancing water usage and ecological protection (Rosenzweig 2003; Grimm and Lund 2016).

Water Quality

Water quality to meet human and ecological objectives is a critical aspect of water delivered in and from the Delta (Lund, 2016). The constituents of major concern in Delta water supply reliability estimation include salinity, disinfection by-product precursors (especially bromide and dissolved organic carbon), and nutrients. Detection and toxicology advances are likely to increase water quality requirements and costs for the future (Delta ISB 2018; Hutton and Chung 1991; Chen et al. 2010). A previous Delta ISB review of water quality science in the Delta provides a broader discussion of Delta water contaminants (Delta ISB 2018).

Water quality is fundamental to Delta water source reliability. Salinity and its management are the most important Delta water quality considerations for water supply reliability. Intrusion of ocean water via San Francisco Bay can have detrimental environmental effects in addition to compromising water exports from the Delta (Gartrell et al. 2017; Reis et al. 2019). Operations and planning models sometimes have sophisticated representations of water quality aspects of system reliability (Jayasundara et al. 2020). A major concern as sea level rises is that greater Delta outflows or new infrastructure will be required to prevent permanent intrusion of saline ocean water into the Delta (Fleenor et al. 2008). Delta salinity barriers, other channel modifications, diversion locations and configurations, and their operation all have great potential to affect water quality and flows needed to support environmental and human water uses.
Harmful algal blooms (HAB) triggered by nutrients and residence time are an increasing concern for recreational, drinking, and environmental water quality in the Delta. Both real and potential occurrences in reservoirs affects water system operations.

Although not always considered, water temperature is important to protect species as demonstrated by failures in managing reservoir water temperatures during the drought of 2012-2016 (Durand et al. 2020). Failure to consider water temperature in models or inaccuracies in data and modeling for temperature can lead to overestimates of water availability that result in fish kills such as occurred in 2014 and 2015 for endangered winter-run salmon downstream of Shasta Dam. Water temperatures with climate change might also affect water supply operations by affecting water demands for ecosystems.

**Science for Water Quality Reliability**
The ability to regulate, forecast, and operate while simultaneously addressing water quality concerns is important for environmental, urban, and agricultural water supplies. The California Department of Water Resources already conducts water quality forecasting for municipal supply (Municipal Water Quality Investigations (MWQI)). Improved ability to quantify water quality effects on water supply is essential to justify and determine appropriate water quality investments, operations, and regulations (Kumpel and Nelson 2016).

Combined hydrodynamic and water quality modeling is the most rigorous and transparent way to understand water quality in the context of flows and habitat development. The California Department of Water Resources and several consulting firms and research centers have developed extensive Delta flow and water quality modeling capabilities, based on a range of 1-dimensional to 3-dimensional hydrodynamic models.

Consolidating and improving such modeling will be essential for adapting the Delta and its water operations for sea level rise, new infrastructure, island failures, habitat restoration, and improving the health of ecosystems. Such modeling capability also provides a framework for integrating and applying scientific results, as well as identifying important science and data needs, in an adaptive management sense, and designing effective monitoring programs (Delta ISB 2018).

**Technical and Management Challenges**

**Portfolios for Water Management**

Until recent times, water supply systems usually consisted of the simple use of a single reservoir on a single stream to supply a single water demand. Much of the
success of California's modern water systems stems from incorporating multiple water sources with multiple storage locations (surface and groundwater) and combining long-term and episodic management of water demand. Operating both supplies and demands conjunctively for planning and operational horizons is known as portfolio management. This natural evolution of water system management as a portfolio of sources and demands has been used for decades, and was formalized as state policy in 2019 when Governor Gavin Newsom issued executive order N-10-19 to state agencies to prepare a water resilience portfolio for California.

Potential portfolio elements are summarized in Table 4. Their adoption can create complex water supply systems that often involve water trading, flexible operations, water conservation, and contracts or agreements with neighboring and distant water systems. This complexity creates water systems that are far more reliable and cost-effective than when these systems are isolated. Figure 7 shows the broad portfolio of sources and infrastructure involved in water supply reliability analysis for the Municipal Water District of Orange County.

Figure 7. Water supply management portfolio for Municipal Water District of Orange County (MWDOC 2018)

Water supply reliability results for such complex systems involve operating decisions for each of the portfolio elements. This is illustrated in Figure 8 for an agricultural water user. With low annual surface water delivery rates, the agricultural user may purchase water for trees. At slightly higher rates of annual delivery the same user may fallow annual crops, or pump more groundwater. At even high levels of annual surface water delivery, the water user may have surplus water to bank, sell, or exchange.

This agency integration highlights the importance of agreements, contracts, regulation, and forms of persuasion that help coordinate a water system's many parts, with resulting interdependence for overall and individual water supply reliability. Modeling such complex and extensive systems, as well as systems of
systems is challenging given unavoidable discrepancies and errors in data and model representations.

Managers of water projects, water and irrigation districts, and farms and households all can act to reduce water shortages and minimize economic and other damages from droughts and other forms of unreliability. In the 2014 to 2015 drought year, farmers statewide lost about 30 percent of their normal water supplies, but the availability of groundwater and water trades reduced shortages to about 10 percent of crop water demands. By allocating this on-farm shortage to less profitable crops, farmers further reduced loss of net farm revenues to only about 3 percent, including additional costs to pump groundwater (Howitt et al 2015).

In California, MWDSC’s integrated water planning analyses comes closest to routinely representing the broadest range of portfolio and reliability elements (MWDSC 2015). Urban water systems, particularly in southern California, have tended to be leaders in explicitly combining portfolio management and reliability analysis (MWDSC, MWDOC, SDCWA, CCWD, EBMUD, SCVWA, etc.). Agricultural systems in California also benefit from the adaptability of more diversified water supply portfolios (Mukherjee and Schwabe 2015). Broad portfolio approaches also have been applied in academic studies to London (Matrosov et al. 2013, 2015); Sydney, Australia (Kidson et al. 2013; Sahin et al. 2017); Baja California, Mexico (Medellin-Azuara et al. 2009); Los Angeles (Porse et al. 2017, 2018); and California overall (Tanaka et al. 2006; Dogan et al. 2019; Arnold 2021).

![Figure 8. Illustrative portfolio components of water delivery (in taf) shown as cumulative non-exceedance reliability for an agricultural user.](image)

Figure 8. Illustrative portfolio components of water delivery (in taf) shown as cumulative non-exceedance reliability for an agricultural user.
California has greatly benefitted from a portfolio approach to water management (Lund 2016). Sophisticated integration of water supply, demand management, and incentive policies provide more reliable, economical, and environmentally effective performance of water systems. Portfolio-based systems can be far more adaptable and encourage agencies to collaborate. The mix of actions and policies improves physical and institutional flexibility to adapt to changing conditions such as droughts, new regulations, and climate change.

Despite the advantages of an integrated portfolio approach, discussions and surveys for this review confirmed that modeling efforts focus mainly on surface water delivery reliability, particularly in state and federal agencies, rather than including groundwater, which is the largest water storage for major droughts. Both water demand management and groundwater management often are neglected portfolio components in discussions and analyses.

Explicit analysis of management portfolios would identify more promising sets of activities and provide insights for their selection (Lund 2016), but will require better representations for some portfolio elements. A more holistic approach is needed to include actual water management conditions, options, and decisions. More transparent, collaborative, and publicly-available data, models, and model development and testing should allow more agencies and water uses to benefit, negotiate, and collaborate with a more common technical enterprise developed in less adversarial settings.

The 2014 Sustainable Groundwater Management Act (SGMA) is placing new pressure on water users and regions that have depended on groundwater overdraft to apply a portfolio approach for their water supply planning (Questionnaire #6). Overdrafts will not be permitted once SGMA is fully implemented in the coming decades. Conjunctive use of surface water and groundwater has ancient roots in California, dating back to the establishment in 1929 of the Santa Clara Valley Water District (now known as Valley Water). SGMA brings new demands and opportunities for improving integration of groundwater modeling and management in regional and statewide water systems (Dogan et al. 2019; Escriva-Bou et al. 2020; Arnold 2021). Implementation of Governor Newsom’s 2019 executive order for water resilience and implementation of SGMA should encourage water systems to adopt more complex management portfolios.

**Science for Improving Portfolio Analysis**

Much of California's recent water supply successes have been due to aggressive development of portfolios of water supply, infrastructure, and demand management at local, regional, and statewide scales. Many urban water supply
modeling and reliability studies include these approaches explicitly. However, many state, agricultural, and regulatory analyses include a narrow range of management options. This also is true for ecosystem and environmental management where our ability to represent ecosystem performance requires further development.

Droughts, reduced surface water availability, and overuse of groundwater have stressed the Delta and other water supplies. These and tightening regulations from SGMA encourage water managers to diversify supplies and management means to meet water demands. Diversification includes underground and surface storage, water transfers and markets, conservation, recycling, storm water capture, desalination, oil-field produced water, and desalination (Arnold 2021). Major water infrastructure projects, such as of the long proposed cross-Delta conveyance have seen little progress and are still being revised, but might be critical to slow or arrest reductions in water supplies for the Bay Area, the southern Central Valley, and southern California.

**Environmental Adaptive Management**

Recent declines of populations of native species in the Delta indicate that managing water and habitat for most ecosystems needs has not been successful. Ecosystems are complex and understanding of interrelationships is often incomplete. Flows that support one species may be detrimental to another (Yarnell et al 2015; Whipple and Viers 2019). Socially defining ecosystem objectives is controversial and there are sometimes water supply conflicts across ecosystem objectives, as well as with urban and agricultural water supplies.

Water supply reliabilities often are over-estimated, which prompts curtailment of environmental flows when water shortages occur. There is a need to conceptualize and analyze more adaptively with all water uses, including contingencies for shortage management.

Adaptive management will need to be applied to track changing conditions and modify supplies to achieve goals. Because effects of drought on ecosystems have not been comprehensively investigated (Lund 2016; Durand et al 2020), and droughts are expected to become more extreme, adaptive management systems that monitor ecosystem responses and provide data and management guidance for water managers will be needed to support the intended benefits of environmental flows.

*Science for adaptive environmental management*

Integration of water supply reliability modeling for environmental water uses with adaptive management decision-making is needed. This brings many scientific and
management challenges for representing ecosystem performance and demands in system models, including better representing the combined effects of habitat and flows on ecosystems.

Applied dynamic ecosystem models will be needed for this, most likely starting with simplified models and growing in complexity to improve accuracy with understanding. Forecasting applications for such modeling might be the best approach for applied ecosystem model development (DISB 2015; Holling 1978; Bellido-Leiva et al 2021).

**Multiple Objectives and Conflicts in Water Management**

Water management decisions, especially in the Delta, often are driven by multiple objectives. Many aspects of water planning can be treated as multi-objective problems with tradeoffs (Cohon and Marks, 1975; Brill et al. 1982). Models presenting multi-objective results and optimization have become more sophisticated in recent decades, but are not applied widely in water planning and decision making for the Delta (Alexander et al. 2018). The lack of application primarily results from the complexity of ecosystems, insufficient data and representation, and unfamiliarity by decision-makers.

Explicit multi-objective analysis and planning is especially useful to balance public investments. These methods should be particularly informative where political balancing across competing objectives is desired based on a transparent discussion based on scientific information (Cohon and Marks, 1975).

**Science for improving multi-objective analysis**

Pareto-optimal trade-offs for water allocations among agricultural and environmental water uses have been demonstrated, but are not typical in California studies (Homa et al 2005; Vogel et al 2007). Potential tradeoffs also exist for ecosystem and environmental flows among different species and ecosystem locations, such as between Delta outflows for Delta smelt and cold-water flows for salmon at different times and locations during drought (Durand et al. 2020).

Quantifying, depicting, and communicating uncertainties in these trade-offs is another area where more research is needed (Arnold 2021).

Incorporating multi-objective analyses into transparent decision processes is a difficult institutional challenge. However, science-based decision-making is likely to require more explicit integration of multi-objective performance estimates in decision deliberations.
**Forecast-Informed Reservoir Operations**

Forecast-informed Reservoir Operations (FIRO) use real-time data from monitoring stations and weather forecasts to improve reservoir management mostly by allowing more water supply storage to be retained during flood seasons (FIRO Steering Committee 2017). Success rests on the reliability of weather forecasts and the operational ability to take advantages of opportunities presented by forecasts for storing water and making flood pre-releases. Ideal FIRO applications are for moderate-to-large reservoirs with ample flood-release capacity, allowing appreciable flood control storage space to be evacuated within the flood forecast period (Yao and Georgakakos 2001; Nayak et al. 2018; Delaney et al. 2020).

Much of California's annual precipitation and streamflow derive from a few large storms (i.e., “atmospheric rivers”) that are somewhat predictable with a lead-time of several days (Lavers et al. 2016). This has inspired integration of atmospheric river forecasts with reservoir management methods (Delaney et al. 2020).

**Science for improving forecast-based system operations**

A challenge is to identify specific reservoirs and precipitation intensities and durations when atmospheric rivers come ashore (Lamjiri et al. 2017). Studies of spatial-temporal variability of atmospheric rivers on a hierarchy of scales and attendant inland precipitation and runoff have some potential to improve operations and performance.

Greatly broadening forecast-informed operations beyond single reservoirs to more integrated forecast-informed operations of more complex systems is a promising research area. Complexities include multiple reservoirs, support for environmental flows, upstream and Delta diversions, and groundwater recharge.

**New technologies for data and model runs and management**

Many new technologies, methods, and practices are available to improve data, models, and model runs that are the backbone of water supply system reliability analysis. These include: improved approaches and documentation for data management, access, and transparency; use of web services to share data, model runs, and post-processing; machine learning (learning empirically from the vast amounts of data available as opposed to explicit model formulations); and approaches to test performance over wide ranges of system conditions.

Advances in computing are making it possible to perform sensitivity and Monte Carlo analyses, as well as more sophisticated optimization analyses that would have been impossible a few years ago. Web services such as GitHub make it far easier to disseminate version-controlled code, documentation, and data.

**Improved Regional Management**

“Any system of water works must be accompanied by a system of human enterprise that involves the allocation, exercise and control of decision-making capabilities in the development and use of water supplies.” - Ostrom, V. and E. Ostrom (1972)

The Delta’s complexity requires integrated efforts to manage limited water resources subject to many jurisdictions. Agency authorities must deal with complex and interdependent administrative and technical authorities and capabilities. Given changing conditions, management must be adaptive, something which can be aided by organized science, modeling, and analysis (Holling 1978).

**Science for improved regional management and cooperation**

Improved management, somewhat greater standardization, and co-development of analytical studies and expertise might help the Delta’s many agencies more effectively employ science to manage the Delta’s changing problems, including those related to water supply reliability.

Information on interdependencies between critical water infrastructure elements, including ecological response, during system failure as well as incorporation of human intervention in controlling the response is a critical need for fragility models. System modeling of water management portfolios for diverse and changing conditions with optimization and probabilistic uncertainty where appropriate can help focus decision and policy discussions on promising alternatives.

**Modeling and Managing Uncertainties**

Analysis, preparations, and data management are important aspects of managing water given the many uncertainties involved.

**Uncertainty Analysis and Preparations**

\[
\text{Risk} = \text{Probability} \times \text{Consequence}
\]

Managers of critical infrastructure must prepare for a wide range of contingencies, ranging from routine emergencies and opportunities to unusual, rare, and even surprise events. These contingencies can involve any human, natural, or
mechanical event that threaten a system's performance (droughts, floods, chemical spills, a wide range of accidents, mis-operation, labor strife, sabotage, regulations, lawsuits, etc.). Routine and periodic maintenance, training, inspections, and other actions also reduce the likelihood of such unfavorable events. Organizations prepare for expected and unexpected contingencies by modeling and in-person emergency response exercises, stocking spare equipment and parts, training, maintaining a network of suppliers, experts, arranging mutual aid with nearby systems, and maintaining individual and organizational capacities for responsiveness and effective action.

Analysis for preparing, planning and allocating resources for the many forms of unreliability should be based substantially on the expected relative likelihood of each contingency, particularly for the most threatening and damaging events (i.e., those having the highest risk). Reliability estimation assesses the probabilities of such events.

Because there is uncertainty in both probability estimates and event identifications, however, there is a substantial likelihood of error in probabilistic analysis and surprise from unexpected events. Thus, it is wise to prepare for a range of especially threatening contingencies, even some beyond what might be justified by probabilistic risk analyses.

For operations, planning, and policy purposes, four types of events can be considered, each of which requires different types of analysis:

1. **Routine events** are so frequent that we prepare for them without feeling a need to estimate their frequency or probability. Stocking routine spare parts, basic safety preparations, communications systems, and personnel training are often in this category. Many pipeline and mechanical failures fall into this category.

2. **Probabilistic events** can be frequent and infrequent but are usually fairly well defined. Relative frequencies are estimated using historical or modeling analyses for balancing outcomes and costs in planning, preparation, and operational decision-making. Most drought and flood planning falls into this category, probabilistically considering hydrologic uncertainty.

3. **Identified events** are analyzed as contingencies, and can include probabilistic events as well as events rare or ill-defined enough that we cannot estimate probabilities. However, we often give forethought and perhaps preparations to these events if their consequences would be great. For example, few
water utilities do explicit probabilistic planning for earthquakes, but most have contingency plans for earthquake response.

4. *Surprise events* are events we have not identified, but we prepare for generally through other emergency training and response exercises, stocking of tools and materials, and mutual aid arrangements with other agencies. For example, most water agencies did not have a contingency plan for a COVID-19 event, but other contingency planning and general preparations were helpful in providing capabilities and disaster-response thinking that could be adapted to an unforeseen surprise to prevent it from becoming a worse catastrophe.

Box 2 summarizes many of the sources of climate change uncertainty in water supply reliability estimation.
Box 2: Uncertainties in climate change studies of water supply

California’s climate is changing, but most details remain substantially uncertain. Temperatures are getting warmer and runoff is shifting from spring to winter. Weather extremes also seem to be becoming more frequent and extreme. But exact details of how and how much California’s climate and hydrology are and will change remains uncertain.

Most climate change estimates are based on a series of model results and statistical corrections, each of which can be done in different ways, and have somewhat different results (Barsugli et al. 2009). These climate change estimates begin with one of potentially many potential future greenhouse gas emission scenarios. Global circulation models (GCMs) then estimate future global climate impacts, usually in terms of temperature, precipitation, and wind results (Sarofim et al 2021). There are many such models, which give somewhat different results for California. These model results tend to differ from recent climate records, and so are often “bias corrected” in one of various ways to better match recent observations (Bane 2020; Teutschbein and Seibert 2012).

The resulting temperature, precipitation, and wind time series results are coarse, determined by each GCM’s computation grid (50-100km). To be used for water supply reliability analyses, GCM results must be then downscaled, by one of various methods, to finer watershed scales for water studies (Wood et al. 2004). The effects of these climate results on future basin land covers and vegetation also must be estimated, through modeling relevant natural and human processes. These climate and land cover estimates can then be input into one of many basin precipitation-runoff models to estimate future streamflows (Schreiner-McGraw & Ajami 2020; Rakhmatulina et al. 2021). Future water demands to estimate water supply reliabilities and shortage probabilities also are needed and are usually estimated separately. Water system models, using these estimates with different representations of future management adaptation are usually the final analytical synthesis for water supply reliability studies with climate change.

As a result, the overall uncertainty and variance of water supply reliability estimates in climate change studies should be much larger than for studies without climate change.

Layers of Climate Change Estimates and Uncertainties

1) Greenhouse gas emission scenarios
2) Results from Global Circulation Models (GCMs)
3) Bias correction of GCM results
4) Downscaling GCM results to local watersheds
5) Estimates of future land cover and vegetation
6) Results precipitation-runoff models
7) Future water demand estimations
8) Future management adaptations
**Science for better uncertainty estimations**

A major difficulty facing water managers is how to prepare for new and sometimes unanticipated events or conditions. Extraordinary events such as natural disasters (floods, extreme droughts, earthquakes, wildfires, harmful algal blooms, etc.), terrorist attacks, war, epidemics, and human error can drastically affect water supplies. Vulnerability to such events occurs both for individual components and in overall water systems with cascading failures. Further development of tools to prepare and respond to emergencies is needed to resist, absorb, accommodate and quickly recover from catastrophic events.

Each component of a system responds in specific ways, affecting others, and the integrated response is complex and often nonlinear. Environmental fragility models focus on this integrated response, while dealing with individual elements of the system. Some such analyses will be probabilistic, but many will take the form of contingency scenario planning. Modeling for general adaptive capacity is likely to be valuable.

Quite a range of numerical experiments using mostly Monte Carlo type techniques should be able to give both analysts and decision-makers much better feel for the largest and most important uncertainties in major models and common important problems. The lessons from these numerical experiments should be useful to both understand uncertainties and prepare recourse options for both favorable and unfavorable circumstances.

**Hydrologic data fundamentals, adjustments, and error analysis**

Various new approaches are available for making consistent and systematic adjustments to hydrologic data to reduce and characterize error (Kadir 2017). There is a difference between raw data (e.g., point field precipitation or ET data) and processed data (which can be spatially distributed estimates of precipitation or ET for use in models). Systematic data adjustments and input data modeling can improve water accounting and form a better basis for Monte Carlo studies involving hydrologic errors. These efforts should also include closer and more consistent linkages between groundwater and surface water models and data.

**Science for hydrologic data and error analysis**

A wide variety of approaches can be taken to error analysis for water supply reliability studies. These include various statistical (analytical, Monte Carlo, sensitivity, etc.) and stress-test techniques (Kadir 2017; Pasner 2021; Kuria and Vogel 2015).
A standard multi-agency State water accounting framework would improve the technical coordination and quality control for water supply reliability modeling, as well as a host of other regulatory and operations concerns in California. Such a framework might be standardized through the water data SCADA systems already employed by major local and regional water agencies.

Establishing some basic standard for error analysis might be useful for helping analysts and decision-makers understand the importance (or unimportance) of various likely sources of error in water supply reliability and other analyses. An interagency technical standards board, including some outside experts, might be useful to help establish and oversee research for such purposes.

Although each of the preceding trends is generally treated independently, the review discussions and survey results confirm that water planning and operations would benefit by explicitly considering these trends together in an integrated way. For example, development of complex portfolios (and even simple portfolios) often must consider environmental flows and their impacts on species and ecosystems; water quality; and climate change. The future must be managed with all these trends in mind.

5. Quality Control in Reliability Estimation

“In all hydraulic data the probable error of measurement is considerable. There is, therefore, no justification for the application of extreme refinements in methods of calculation.” Allen Hazen (1914, p. 1541)

Water supply reliability estimates are important for project planners, water managers and users, regulators, and a wide variety of decision-makers faced with evaluating and judging the performance and trade-offs of decision alternatives. These important, expensive, and often time-consuming decisions can require difficult and complex discussions, multiple proposal iterations, and technical controversies regarding supply reliability for various water uses. Decisions usually are implemented with specific agreements or requirements informed by reliability estimates.

This section reviews and examines unreliability in water supply reliability estimates, and discusses approaches to quality control in water supply reliability estimation.

Why Water Supply Reliability Estimates Differ

Analyses to estimate water supply reliability require an organized representation of water sources, water demands, and the water management system (as shown in
Figure 2). Each representation usually requires many subsidiary representations and judgements. These representations are approximate, especially when they apply to the future. Thus, any two modelers will likely make different estimates of water supply reliability, even where they agree substantially in their representations (Lund 2016). Future reliability estimates are uncertain and probabilistic (Jaynes 2003).

The quality and uncertainty of water supply reliability estimates depend on the representation of inputs, infrastructure and its operations, and demand expectations. In California, traditional water delivery reliability estimates employ water system models, e.g., CALSIM II, CALSIM 3.0, Cal-Lite, SACWAM, and CV mod. All these models have some accounting for water demands, regulations, network dynamics, infrastructure, and operating policies (Lund 2016). Because these models and their variants are specialized, a potential vulnerability is that modelers may become preoccupied with learning and running the model narrowly, without being critical of the broader realism of model outputs or the decision-making usage. Turnover of modelers in agencies has been an annoyance, and retaining experienced personnel and developing a cadre of modelers who are at different career-stages should be a priority.

Estimations of water supply reliability can diverge with representations in the broad components in Figure 2, as summarized in Table 5 and discussed below.

**Table 5. Why water supply reliability estimates differ**

*Hydrology of water sources.* Water supply systems can have many surface water, groundwater, and reuse sources, which may be represented in different ways, especially when considering different future climate and regulatory scenarios. Water accounting is imperfect with many estimated components (Escriva-Bou et al.

52
Quantities such as precipitation, streamflow and water exports are relatively well measured/estimated and documented for the Delta, and extensive water monitoring networks cover most large watersheds, but even small uncertainties can have high decision value, when the market value of water in drought exceeds $1000/acre-ft (DWR 2018). The hydrology of each source must be represented and estimated, usually as a time series of available streamflow, runoff, aquifer inflow, or reuse water availability. Estimating these quantities over time is particularly approximate for extreme wet and dry conditions, especially with a changing climate.

Hydrologic inflows usually are based on historical records of unimpaired streamflow or a synthesis from outputs of climate models. Most water supply reliability modeling considers only the historical hydrology with little account of anthropogenic changes in demands, regulations, and operations and other uncertainties in upstream and downstream inflows. An ensemble (e.g., Monte Carlo) approach might better represent a diverse set of dynamic scenarios. Currently MWDSC runs as many as 17,000 plausible, but not probabilistically representative, future scenarios (MWDSC 2015). MWDSC and Santa Clara Valley Water District also run probabilistic scenarios based on re-sequencing the historical hydrologic record (MWDSC 2010; SCVWD 2003).

More substantial hydrologic gaps and uncertainties exist for groundwater storage, flows, pumping, basin evapotranspiration, snow cover, melt rates and upstream precipitation (Medellin-Azuara et al 2018). Water use by surface water rights holders is often poorly reported, only applied and not consumptive use is reported, and groundwater withdrawal remains unreported. Return water to the system after usage is sometimes not properly reported (Lund 2016). High frequency (e.g., sub-monthly) data are more prone to error than monthly or annual counterparts. Synthesis between data sources, identification of flaws/inadequacies of measurements leading to divergent data, and stronger error estimations and documentation may help improve input data quality (Kadir 2017; Pasner 2021). The monitoring tool that ESSA developed for Delta Science Program can be useful for some data gaps, duplication, and uncertainty and quality estimates (Alexander et al. 2018). Appendix A further discusses some issues in representing hydrologic inputs for water supply reliability analyses.

Currently federal and state agencies in California maintain multiple computer models, but coordination in their development and use could be improved. Establishing a common or standardized water accounting framework for water (in and outside the Delta) with consistent and contextual monitoring, evaluating and reporting protocols is highly desirable (Escriva-Bou et al. 2020b).
Water demands. Complex water supply systems also tend to have fluctuating and changing water demands, for various urban, agricultural, and environmental uses. The complexity of water demands is simplified for modeling, but becomes more complex when water conservation/demand management activities are considered in the reliability analysis. Major urban areas are seeing diminishing per-capita water use rates and commonly manage water demands by voluntary or mandatory rationing during drought to shape the frequency and depth of water shortages and employment of alternative water sources. Some agricultural water users reduce water use in lower-valued crops differentially across wet and dry years to increase aquifer recharge, shift water to higher valued crops, or sell water (Howitt et al. 2012, 2015).

Fuller testing and documentation of water demand representation would help understand the likely range of reliability model accuracy. Water demands in models usually are based on land uses that are frequently considered fixed. Agricultural water demand estimation is hampered by lack of field data at appropriate space-time scales. Appendix A further discusses some issues in representing water demands for water supply reliability analyses.

Model structure and representation of the water supply system. Models used for water supply reliability have structural and detailed differences, often including different portfolio elements and representing their interactions differently. Different modelers also usually apply these models differently. All models have intrinsic advantages and disadvantages. There can be a significant spread in water supply reliability predictions, despite reasonable differences in modeling assumptions (Lund 2016).

More detailed internal water network reliability assessments also are common. Simpler analyses estimate the probability that all users are connected to at least one source, based on combining probabilities of individual network component failures. This topological reliability uses network theory. In more elaborate hydraulic reliability estimates, the probability that a water supply system provides adequate supplies to each user is estimated using stochastic (Monte Carlo) simulations, where random events out of the component reliabilities are generated, and the cumulative performance of the system is summarized with performance statistics. Hybrid methods combine the two approaches (ASCE Task Committee on Risk and Reliability Analysis of Water Distribution Systems 1989; Hossain et al. 2020).

Water supply reliability estimation is challenged by random and non-stationary processes such as population growth, land use change, climate variability and
change and unexpected (black swan) events. Models often need to be nudged to account for these. Climate change effects on the Delta are likely to be significant, with water export reductions of about half-a-million of acre feet while diminishing ~25 percent of the north-of-Delta carryover storage by 2060 (Fleenor et al. 2008; Wang et al. 2018; Knowles et al. 2018). Such non-hydrologic non-stationarity has potential to change the model details, capacities, and portfolio structure over time.

Modeler and modeling practices. Classically, model errors are attributed to error in model structure (formulation), model parameter estimates, model input values, solution method, and results interpretation. All of these are under the domain of the modeler and the modeling culture of the performing organization.

Despite a few efforts at convergence, water supply reliability modeling organizations can have different modeling cultures, and individual modelers have different experiences and judgements. Many water supply reliability studies are minimally documented or inaccessible, making it difficult to assess their reliability. Model results rarely include substantial error analysis (although Hazen did this in 1914). Given the sophistication of reliability estimation models, agencies often are reluctant to invest in laborious and expensive efforts to analyze and document model performance and improve models.

The water management community might benefit from some broader expectations and efforts that include quality assurance, error analysis, and evaluation. Quality control for modeling, system analysis, and their applications to California water problems are long-standing topics (Tetratech 2019a, b; CWEMF 2021; DIB 2019; ongoing USBR and DWR efforts for CalSim). Almost all modeling efforts have some quality control (without which modeling would devolve into piles of random calculations and numbers). Recent years have seen increasing professional expectations for quality control in model development and applications, with related expectations for documentation of models and data, transparency, reproducibility, accessibility, as presented below.

Making Analysis Transparent, Documented, Replicable, and Accessible

Attributes of desirable modeling practices are well described (Tetratech 2019a, b; CWEMF 2021). Today, most quality controls on water supply reliability modeling are internally-facing for the conducting organization, not reflecting explicit external technical expectations. No method is universally accepted to quantify the quality of water supply reliability analyses (Thissen et al. 2017).

Professional expectations for water supply reliability studies, and technical studies in general, tend to be based on the professional culture of individual and collective
practices. In fields without a common modelling institution or professional organization where expectations can form and perhaps be codified, divergent quality control efforts often take root.

Expectations for professional practice can be informal, often patterned after templates or exemplars of practice or formalized, but less flexible, as standards, legal or regulatory requirements, and analysis contract language. Professional practices often are manifest in model, data, and analysis documentation, testing, and availability. The state-of-practice of quality control for various components of water supply reliability analysis based on our experience is summarized in Table 6 and discussed below.

Table 6. Common quality control effort levels for documentation, testing, interpretation, and availability of components of water supply reliability analyses: models, input data, results, and overall studies and reports

*Documentation.* Models dealing with complex coupled natural-human-engineered systems have unavoidable deficiencies, uncertainties and quality of data, so it is essential that clear public documentation of modeling methods, assumptions, building blocks, and underlying uncertainties are available, and where appropriate published in peer review literature. Such expectations for documentation are only occasionally met.

*Testing.* System models for water supply reliability estimations can be tested in multiple ways. These include model-data comparisons, model code verification, sensitivity studies, and more formal error analyses.

Development of new models or upgrades and adaptations of existing models (e.g., future CALSIM-4) provide new capabilities. These can include higher spatial/temporal resolution (e.g., daily, weekly), changes in water sources and infrastructure (groundwater, land use, water reuse, reservoirs, conveyance, treatment), dynamics (non-stationarity), bottlenecks (algae blooms, clogging, engineering failures), multi-benefit (ecological, water quality) considerations and economics, and perhaps more explicit sensitivity and uncertainty analyses.
Models can be tested against field data and logic. For short-term operating purposes, comparisons of field data with model data are a foundation of model reliability, providing timely insights to assess and improve model accuracy and utility. However, for longer-term policy and planning application model-data comparisons the most relevant field data will be unavailable until long after planning decisions must be made. Thus, field data for longer-term planning analyses must be extrapolated, sometimes crudely, from historical or recent conditions, usually for component process models (such as household or crop water demand models).

Models can also be tested based on the logic, theoretical, and literature validity of their structure and parameter values, and assumed inputs. These can be vetted with experts and stakeholders, particularly if they are well documented. Error analyses can propagate presumed or estimated errors in model components to estimate likely model errors in outputs. When models are applied to more distant futures or operating conditions further outside their range of calibration, larger errors should be expected and prepared for, and testing must be based more on logic, error analyses and formal reviews.

The logic and behavior of most models are tested primarily by comparing their assumptions and results against the understandings of the system by the modelers involved, as well as operators, managers, and stakeholders. Sometimes these tests are fairly extensive prolonged, and iterative processes, with some documentation, ending with a more accurate and trusted model.

Sensitivity analysis is a process which varies various model assumptions to assess how much model results and conclusions might change. This is a common approach to testing model results and conclusions (Vicuna et al. 2007). Sensitivity studies can be very insightful, especially when a wide range of possible future conditions are explored. It has been used and developed extensively as “decision-scaling” or “robustness” analyses (Brown et al. 2012; Wilby and Dessai 2010). Most “robustness” planning examines the performance of alternatives based on many possible future scenarios (usually not probabilistic) to assess ranges of unfavorable and favorable future conditions (Wilby and Dessai 2010; Means et al. 2010). The “decision-scaling” approach is especially promising in that it uses fewer, more artfully designed, scenarios representing sequentially more dire conditions to assess the range of stable and desirable performance for a system or a proposed alternative (Brown et al. 2012).

Error analysis is a more formal form of sensitivity analysis, which makes probabilistic assumptions about the likelihood of various model input or parameter
conditions (Hazen 1914; Shuang et al. 2014). Error analysis can be done analytically (Hazen 1914) or more flexibly as Monte Carlo studies (Klemes 1987; Nayak et al. 2018). A limitation of both sensitivity and error analysis approaches is how to handle the many (often hundreds or more) assumptions involved in reliability estimation, and how these conditions might be correlated across variables and in space and time.

To be better able to test and compare models and model results, greater standardization of data and modeling is recommended, discouraging the current silo approach and building in-house or closed versions of the model that act as black boxes. American Water Works Association (AWWA) and International Water Association (IWA) have developed standardized methods for water audits that assist completing water balances. Periodic audits can be a part of reliability estimates (Sturm et al. 2015). Having such results documented and accessible can be helpful.

**Expert Interpretation.** Initial model testing already employs the scrutiny of model and domain experts. Routine model results, and reliability estimations, also can benefit by adding written interpretations and discussions of results by model and problem experts for problem-oriented managers. The documentation of interpreted results can make their reasoning more explicit and useful for a broader range of interested parties.

**Review.** Internal reviews almost always occur of water supply reliability studies and of the system models used to produce them. However, external reviews are less uniformly applied but may be advisable to promote use of current science. For example, in California, the CALSIM II model has been formally externally reviewed for journal publication (Draper et al. 2004; Islam et al 2011) and sometimes in more depth, sponsored by the California Water and Environment Modeling Forum (CWEMF) (Ford et al. 2006; Close et al. 2003). Local system models are sometimes also reviewed externally (Randall, et al. 1997). Elsewhere, the major water supply reliability modeling system used by New York City recently was reviewed by the US National Academy of Sciences, Engineering, and Medicine (NASEM 2018).

**External replication.** Replicability is a staple of scientific work. Sometimes replication efforts are made of water supply reliability and other analyses. An example is MBK Engineers and Steiner's (MBK 2014) report on their attempt to repeat several BDCP water supply reliability modeling analyses done for the Department of Water Resources (DWR 2015). Another example is a recent re-analysis of San Diego County Water Authority proposals for a second Colorado River Aqueduct (Elmer 2020). Some recent efforts have been made in the water
engineering profession to make replication testing of modeling and technical work less onerous and more common (Stagge et al. 2019; Rosenberg and Watkins 2018). Some such comparisons are what might be called adversarial reviews intended for regulatory or court proceedings or negotiations. More such comparisons are likely to be done internally.

For long-term planning studies, such re-analyses often give substantially different results, which is not surprising given the many assumptions and uncertainties involved over long planning horizons. There is often a tendency to over-interpret reasonable but substantial differences in results in adversarial discussions, rather than using these differences as indications of inherent uncertainties in the estimation problem and the wider range of contingencies that need to be prepared for.

**Availability.** Having documentation, data, and models available is an important aspect of quality control directly, to support other quality control processes (replicability, etc.), and to improve understanding of water supply reliability results and their limitations.

The availability of documentation for studies and models in California has improved markedly in recent years, with the posting of such reports on agency web sites becoming a common practice. However, there has been a nearly wholesale removal of such reports and documents from State agency web sites, since the documents did not comply with accessibility requirements for persons using assistive technology (Venteicher 2019). This is leading to much of the details of California’s water system, history, and analyses being effectively lost.

Data availability in California is better than in most parts of the world, with streamflow and other data being commonly posted, and modeling data being posted commonly for some agency programs. In recent years, the profession has devoted some efforts to document and standardize data and data management, which should speed new model development, as well as testing and improvement of existing models and model results (Harou et al 2010; Rosenberg and Watkins 2018; Knox et al. 2019; Abdallah and Rosenberg 2019; Stagge et al. 2019).

Although publishing system model codes has not been common, it is becoming a common expectation in California and elsewhere. The [modeling software for CALSIM](https://www.wrcal.org/technical-software) (as well as its input data sets) are often available from DWR. The newest Python version of the CALVIN network optimization model for California is available on GitHub (Dogan et al. 2018). Elsewhere in the profession, a generalized water resource network modelling Python library, Pywr, is now available (Tomlinson et al. 2020).
As indicated in Table 5, quality control for technical work has many facets, especially for controversial public policy problems. Considerable progress is being made in quality control for water supply reliability estimation in California, but additional benefits for technical efficiency, understanding, and improved discourse will result from further informal and organized efforts in this direction.

**Common Basis for Water Supply Reliability Estimates**

Various efforts have been made to support a common basis for water supply reliability estimation. Some such efforts are discussed by Jackson (2006, 2005). Several multi-agency efforts in California include:

1. **The California Water and Environment Modeling Forum (CWEMF):** The Forum meets regularly in annual meetings and workshops to discuss modeling advances and issues. The Forum fosters technical information exchange among agencies, and has organized several modeling reviews for CALSIM (Ford et al. 2006; Close et al. 2004). It currently is developing modeling guidelines (CWEMF 2021).
2. **California's DWR and the federal USBR:** These two large state and federal agencies jointly developed the CALSIM models used in the SWP and CVP water projects. After 20 years, this model is on its third basic revision. They have a joint effort, the CALSIM Model Maintenance Management (CM3) group, to coordinate development and documentation of these models.
3. **“Common assumptions” efforts:** Following development of CALSIM II, there was a multi-agency (DWR and USBR) effort for several years that was staffed by consultants, to standardize land use, inflows, groundwater modeling, water demands, and portfolio characterization for modeling. Similar efforts continue informally.

Other efforts to provide a common basis for modeling include:

1. **Standard model test data sets:** Algorithmic and historical test sets sometimes are developed and used. Several professional efforts have sometimes been proposed or utilized to improve quality control and documentation of water supply reliability estimates.
2. **Separation of models from input and parameter data:** This is a further extension of the long-standing philosophy of CALSIM of avoiding hard-coding of operating parameters and rules as much as possible. Here, data for the model is stored in separate explicit data bases, often including documentation of the data (much like Draper et al. 2003 for CALVIN). This can greatly improve model and data documentation and ease its understandability and ability to upgrade.
3. **Software-neutral modeling and data standards**: These have been suggested and developed to encourage development, testing, comparison, and documentation of models (Knox et al. 2019; Tomlinsom et al. 2020).

4. **Common water accounting**: An example is the state of Colorado's maintenance of common water accounting across basins for models for water right and water supply reliability (Escriva-Bou et al. 2020b).

5. **Common efforts to estimate uncertainty**: Uncertainty analysis is common in water supply reliability estimation, particularly for seasonal (within-year) operations. However, different agencies perform such analyses very differently. More common efforts to estimate uncertainties in reliability might be useful (MWDSC 2015; Hirsch 1978). In some cases, machine learning methods might be helpful (Lingireddy and Brion 2005).

Integration of various models into a unified platform is a possibility, but it would be time consuming. Integration needs to be a parallel effort in conjunction with ongoing water supply reliability estimates and modeling upgrades. Integration requires expertise from multiple agencies. Integration itself may produce uncertainties, and an evaluation of return on investment is needed.

**Model Updating and System Learning**

As water systems and problems change in California, modeling and analyses will need updating. Classically (Hollings 1978), adaptive management is based on updating models in an organized way to combine scientific efforts and management problems.

More transparent, science-based, collaborative, and open source modeling will help agencies, stakeholders, and the public be more aware of the intricacies, value, and limitations of water supply reliability estimates (e.g., Box 3) (Sarofim et al. 2021). It will inform managers on the accuracy of outputs. Openness and transparency will help pare the criticism of current lop-sided representation of opinions on water supply reliability. The more the transparency, the more arduous it will be to arrive at consensus. Nevertheless, such an approach may help reduce litigation and better support healthy partnerships. Building trust on the quality of water supply reliability estimates should support science-based Delta management in the near-term and long run.
Box 3. Ten “commandments” of software acquisition for the Department of Defense (from DIB 2019)

1. Make computing, storage, and bandwidth abundant to DoD developers and users.
2. All software procurement programs should start small, be iterative, and build on success – or be terminated quickly.
3. The acquisition process for software must support the full, iterative life cycle of software.
4. Adopt a DevSecOps culture for software systems.
5. Automate testing of software to enable critical updates to be deployed in days to weeks, not months or years.
6. Every purpose-built DoD software system should include source code as a deliverable.
7. Every DoD system that includes software should have a local team of DoD software experts who are capable of modifying or extending the software through source code or API access.
8. Only run operating systems that are receiving (and utilizing) regular security updates for newly discovered security vulnerabilities.
9. Security should be a first-order consideration in design and deployment of software, and data should always be encrypted unless it is part of an active computation.
10. All data generated by DoD systems - in development and deployment - should be stored, mined, and made available for machine learning.

6. Reliability Estimation in Decision-making

Water supply reliability estimation is broadly important for water planning and operations in California, but there is a wide range of ideas of how to characterize and estimate water supply reliability for various water uses and purposes in highly varied and dynamic policy and management decision contexts. It is easy to produce a plethora of numbers and statistics on water supply reliability, but it is a challenge to develop estimates insightful for diverse policy-makers, managers, and the public. Using reliability estimations to inform discussions and suggest solutions raises technical and institutional challenges.

Several policy and management questions regarding water supply reliability arose in the course of discussions and presentations for this report, with examples in Box 4. These illustrate the wide range of questions of concern. Formal water supply reliability studies can be designed to formalize and answer such questions.
Box 4. Some water supply reliability questions arising in the course of this review

- Could a water quality reliability contracts between the State Water Project and various in-Delta water agencies better coordinate in-Delta operations?
- How reliable would a western Delta tunnel diversion location be for supplying Delta exports?
- What is the reliability of attaining Delta water quality standards under various future and management conditions and Delta water export levels?
- How is Delta water diversion reliability affected by various Shasta operations for winter-run salmon?
- How do various out-of-Delta water supply and demand management portfolios affect the frequencies of Delta water demands for various operating, environmental, and climate conditions?
- How do various Delta salinity or fish barriers affect Delta water quality and diversion reliabilities?
- How can California climate change predictions be effectively incorporated into water supply reliability estimation for the Delta?
- What are the implications of SGMA for water supply reliability estimates?

**Organizing the Problem and Solutions**

Formal water supply reliability analysis can help structure and organize complex and difficult technical problems for decision-making. Although the problems remain difficult and complex, organizing them should improve policy and management discussions and decisions. Informal or poor analysis can obscure and obfuscate problems and solutions (Rosenberg and Madani 2014). Scientific and technical work is most effective when the analysis is tailored to the decision-making problem and context. Decision-making also benefits when the institutionalized decision process is tailored to employ scientific and technical information.

All water supply reliability analyses share many common elements as described in Section 1 (Figure 2). This provides a rough common structure for organizing problems and solutions. Many details, which involve technical and policy assumptions for future conditions must be specified in each of these representations. These details are often quantified using socio-economic models. A wide range of detailed representations can be employed for any physical and socio-economic water system structure. More formal model and analysis development and testing can better embed technical analysis into decision-making and provide a more scientific structure for the development, understanding, and evaluation of solution alternatives. Water supply reliability analyses tend to be more useful when
they have co-evolved interactively with structured water management decision-making.

**Short-term Operation Decisions**

Short-term water supply decisions include water diversion, conveyance, storage, and delivery operations. These decisions usually extend from daily to seasonal (within-year) periods, and sometimes extend to multi-year planning operations for ongoing or hypothetical droughts. Most short-term operating decisions are routine, having been made collaboratively many times before by both decision-makers and analysts. Regulatory, water demand, and hydrologic conditions are more certain on daily to seasonal timescales (despite substantial residual uncertainties) and better informed by recent experiences. Both analysts and decision-makers often use modeling estimates to refine and test different intuitive ideas, usually based on their expertise and experiences. Because the analysts and decision-making users of model results have worked together for some time, they often have adapted their work and deliberations to be mutually-informative.

Water supply reliability analyses for these short-term decisions commonly use some variant of position analysis or other probabilistic representations of how conditions could likely evolve (Figure 5) (Hirsch 1978; FitzHugh 2016). The results embody many likely uncertainties explicitly, and contingencies for unusual extremes are factored in with various forms of sensitivity analysis and informed professional judgement.

More routine reporting and posting of operational analyses can help decision-makers, regulators, and other stakeholders better understand and employ these methods and results. Better incorporation of short-term forecasts and newer modeling techniques also might be useful (Nayak et al. 2018; Doering et al. 2021).

**Long-term Planning and Policy Decisions**

Longer-term planning and policy decisions include infrastructure changes, water allocation priorities, operating and regulatory rule definitions, and the general balancing of water supply portfolio elements. Such decisions are more varied, less focused, usually less clearly organized, and involve a wider range of interested parties within a less technical and more explicitly political context. Moreover, water demand, regulatory, infrastructure, ecological, and hydrologic conditions in more distant futures are much less certain, making probability estimation more challenging but necessary. Modeling for future conditions is inherently approximate, even though the stakes of the decisions are often larger.
Decision-making in longer time-frames must accommodate less accurate modeling forecasts. Additional modeling time and expense will delay decisions, but may not substantially reduce uncertainties, although futuristic modeling can help explore and compare the likely relative performance and adaptability of different strategies.

In particular, more creative and non-routine modeling can help structure more adaptable contingent decisions more likely to succeed and lead to successful agreements. This requires giving analysts both latitude and direction to explore and compare solutions. The process of developing such a modeling study can help structure decision-making and allow a broader range of solutions to be explored.

For longer-term water supply reliability modeling, probabilistic analysis remains useful, despite the greater uncertainties. Bayesian analyses can help estimate probabilities in such circumstances (Fletcher et al. 2019). Exploratory sensitivity and robustness analyses also are important for such cases.

**Long-term Education and Insights for Policymakers**

Well-crafted modeling analyses and studies are an important way to educate the diverse range of people involved in water management, and to prepare them for likely operational, planning, and policy problems. Decision-makers, policymakers, regulators, stakeholders, operators, and modelers often lack deep background in the breadth of water delivery and water management systems. Changes over time in these systems and their problems makes it difficult for the many groups and people involved in water management decisions to remain informed and use the latest tools. Well-executed, documented, communicated, and available water supply reliability studies all can be important in educating these groups, giving them a more common understanding and ability to communicate in policy and planning deliberations.

Model and model result documentation must serve both detail-oriented audiences and broader management and policy audiences. Good documentation communicates useful model results, and assurances that the understanding and modeling of the system has been appropriately thorough. Documentation of analyses need not be ponderous if model details and methods are documented elsewhere.

In some cases, simplified displays of results will be useful, such as simplified “traffic signal” types of indices (green-yellow-orange-red) for providing continuing water supply status for water availability for human uses and ecosystems.
Potential for Decision Analysis

“The best-laid schemes of mice and men go often awry” Robert Burns 1785

Structuring decision-making to consider uncertainties is a common concern and problem in management and policy. Since the 1950s, the field of decision analysis has developed to help organize and partially resolve such issues (von Neumann and Morgenstern 1944). These methods may help identify less promising solutions to problems and resolve what, on balance, may be the best decision to make, and then structure what to do as conditions evolve. Several Delta problems have been organized and addressed with simple decision analyses (Suddeth et al. 2011; Lund et al. 2010).

In such situations, it is tempting to include elaborate and complex decision analyses. However, more complex decision analyses and analyses at finer geographic scales and shorter time steps are harder to understand and trust, and more subject to errors. Simpler decision analyses are often better for developing a common organization of a problem. A common understanding based on a simpler analysis can be a foundation for additional refinements and error analyses as needed. Complex analyses, when needed, are often completed more quickly, rigorously, and insightfully when grown from simpler analyses.

Although water supply reliability estimates are commonly produced for water managers and policymakers, they vary greatly in quality and insight across the organizations and individuals that conduct them and the operational, planning or policy problems that they are intended to inform. Despite varying widely, these analyses are often useful. But their utility requires some comfort and familiarity by decision-makers, sometimes based on months or years of analysts conversing with operational and policy decision-makers. This artisanal education of agency decision-makers on their agency’s reliability analyses can limit their ability to appreciate and compare results from other agencies or organizations. When multiple reliability studies are done by different groups for the same project, there is often controversy. But often, such controversy exceeds the technical reliability of differences in results.

Much can be learned from parsimonious models tailored for a specific set of problems, but more complex problems and solutions often must be analyzed or tested with advanced modeling. Balancing is always needed between the complexity of models and discourse with policy-makers who may be less cognizant of technical details and assumptions but more cognizant of other important factors in decision-making.
7. Conclusions and Moving Forward

Well-managed diversified water systems are more reliable, adaptable, and suffer less damage from droughts and other water shortages than most simple traditional water supply systems (Lund 2016; Durand et al. 2020). Estimations of water supply reliability are fundamental to the planning and operations of such complex systems, which often require agreements and active participation from neighboring and distant collaborating agencies and water users. Such water supply reliability estimates and analyses also are needed to advance environmental water management and its coordination with water deliveries for agricultural, urban, and other uses over planning and operational time scales.

Most large water systems in California have matured and adapted to include coordinated portfolios of water supply and demand management actions to improve their performance. Estimating the reliability of such complex and often-interconnected systems typically requires computer model representations of interacting physical supplies, infrastructure, operations, institutional priorities and regulations, and diverse human and environmental water demands that vary in space and time. Expansion from water source reliability to estimation of integrated water system performance reliability often involves a range of fundamental performance objectives, as well as some useful technical performance objectives.

Water supply reliability estimation needs to be better incorporated into decision-making processes. Improved documentation, testing, multi-agency modeling, and continuous adaptation would facilitate the application of modeling to decision-making.

Effective water supply reliability analysis and estimates are fundamental to managing water in California, given the State’s broad range of evolving hydrologic, economic, societal, and ecological conditions. Although water supply reliability analysis is common in California and provides useful insights, it often is done in non-reproducible ways without sufficient testing, interpretation, documentation, and public dissemination due to time pressures and inadequate human resources. Improving the scientific basis for water management requires more systematic development for water supply reliability analyses, especially for changing conditions and emerging problems, solutions, and policies.

The COVID-19 pandemic reminds us of an important limit of reliability predictions, when an unexpected surprise rapidly changes the conditions of professional and personal work, through which water supply and other systems must continue to perform. In this case, the extent and depth of pandemic disruption did not disrupt
water deliveries for most uses, demonstrating the adaptability of most water systems to at least some major surprise crises.

Water supply reliability estimation in California and the Sacramento-San Joaquin Delta will have to adapt to many changes, in climate, human and ecosystem water demands, infrastructure, environmental regulations, and probably a few surprises. Water supply reliability estimates are vital to prepare, plan, and negotiate for these changes, individually and collectively. These estimates must be done in the context of California's extreme and growing hydrologic variability, complex and extensive infrastructure systems, changing water demands, and decentralized institutions that bless and curse water management in California.
Box 5. Some common questions on water supply reliability

Is there potential for long-term seasonal and multi-year forecasting?

Short-term forecasts of a few days often provide the greatest improvements in performance, with longer forecasts generally providing diminishing increments of improvement (Doering et al. 2021). Longer-term forecasts also usually tend to be less accurate. In most of California, precipitation forecasts beyond about two weeks are generally show little predictive skill beyond that of historical climate statistics. Long-term seasonal and multi-year forecasts are usually much less accurate than short-term weather forecasts. Seasonal and multi-year weather patterns for some parts of the world do seem correlated with ocean conditions (Chikamoto et al. 2020). For southern California, annual precipitation is mildly correlated with ENSO ocean conditions (Schonher and Nicholson 1989). Long-term forecast accuracy faces a fundamental problem of the chaotic nature of most weather forecasting (Lorenz 1993, Slingo and Palmer 2011). All forecasts are imperfect, with potential to mislead and distract, as well as to provide management insights. For the foreseeable future, historical records, perhaps modified statistically to account for a range of climate change estimates, appear to be the most promising basis for developing forecast scenarios.

Does the export or import of water-intensive products affect water supply reliability?

The fate of products produced using water is usually not included in estimates of water supply reliability. “Virtual water” is the water use embodied in goods which are traded across borders, and is a rough indicator of the amount of water used goods which are exported and imported. The production of water-intensive products does affect water supply reliability, although their export can provide greater economic advantages than producing other products using an equivalent amount of water, particularly in poor rural areas. For economic prosperity in a non-subsistence economy, the economic value of goods produced using water is the same if they are exported or consumed locally (Pfister et al. 2009; Wilchens 2010; Neubert 2008).

How does water storage expansion affect water supply reliability?

Having additional water storage capacity usually requires some, often large, costs for construction, operations, permitting, etc. The additional water supply reliability from these investments varies considerably with the availability of water to fill that capacity, and the conveyance capacities and costs to move water into and out of the storage location to serve water demands. Additional water storage capacity theoretically improves water supply reliability, but not always enough to justify the necessary investment (Hazen 1914; Arnold 2021).

What is the potential for artificial recharge of flood waters for improving water supply reliability?

The recharge of flood waters to aquifers is perhaps the most popular solution for eliminating overdraft in California’s groundwater basins. Several analyses of this source have found that it has some value for this purpose, but that it is unlikely to be able to eliminate most groundwater overdraft in most groundwater basins in California (Escriva-Bou and Hanak 2018; DWR 2018). Flood waters in California are infrequent, hard to capture, and tend to occur in locations far from areas with the greatest groundwater overdraft.

This appendix briefly reviews approaches for representing hydrology, human water demands, time, and decision-making in water supply reliability analysis. The appendix also summarizes approaches to uncertainty analysis for estimations of water supply reliability.

Representing hydrology in estimating water supply reliability

Hydrology is the most commonly explored cause of unreliability in water systems. Several approaches are taken to representing hydrologic uncertainty and variability in water supply reliability studies.

Historical records and different climate models predict different future water availability estimates for California. Ensemble modeling may better represent the uncertainty, but high variability among models raises doubts. The coarse resolution of climate models raise regional and local scale uncertainties from downscaling precipitation and temperatures to local basins, as well as various models for estimating stream runoff and groundwater infiltration from precipitation, sometimes with climate-dependent vegetation and land cover. High resolution multi-ensemble models coupled with innovative downscaling techniques to high space-time frequency hydrologic projections might reduce such issues (Pagan et al. 2016; Grantham et al. 2018). Yet high resolution without better process understanding might not be more accurate.

Traditional DWR delivery capabilities reports cover five year periods, so the climate change effects are minimal unless the reporting period is predicated by extreme events (DWR 2020). Long term planning (e.g. decadal) should incorporate the best projections of climate change, with consideration that these projections are themselves uncertain.

Several approaches to representing hydrologic extremes and variability are summarized in Table 7 and discussed below.
Table 7. Approaches to Representing Hydrology for Water Supply Reliability Studies

<td>Essentially inverse-scenarios, increasing climate change characteristics (temperature, seasonal shift, extreme events) until system performance suffers.</td>
</tr>
</tbody>
</table>

"Design drought" – Many water supply systems often evaluate their system infrastructure and operations based on a repeat of the most severe drought of record, akin to “firm yield” analysis (Linsley et al. 1992). Many urban areas specify design droughts as specified in state law for Urban Water Management Plans, mandated for all large urban water suppliers. EBMUD has developed a drought somewhat more severe than that seen historically to assess the ability of their
system to weather severe droughts. The EBMUD design drought is a three-year sequence where the first and second years have runoff from years 1976 and 1977 (the driest two-years on record), plus a third year with the average runoff from these two years (EBMUD 2021).

*Historical unimpaired flows* – In California, most water supply systems typically use estimates of historical unimpaired streamflows (and sometimes groundwater inflows) in evaluating water supply reliability. DWR's series of water delivery capability reports (since 2002) mostly take this approach (DWR 2017, 2020). In early times, these analyses were used to identify system “firm yield” deliveries. Today, most such analyses develop water delivery-reliability distributions and curves (Hirsch 1978). DWR has an extensive and formal hydrology development process to develop the accretions/depletions developed by DWR-USBR more than 50 years ago as their basis for planning models (DWR 2016). Recent work further refines the calibration of historical unimpaired flows and allows better statistical characterization of likely statistical errors in these flows (Kadir 2017).

*Re-sequenced historical flows* – Resequencing historical streamflows by varying the starting year or by bootstrapping can, in principle, produce larger statistically representative samples of streamflows that include more extreme events (Tasker and Dunne 1997). Because the historical streamflow record represents only one realization of the many sequences that could occur in the future, MWDSC has adopted more of combinatorial approach that develops additional hydrologic time series, with each time series beginning in one year from the hydrologic record, followed by the remaining years of record, followed by abruptly the earlier years of record before the starting year (MWDSC 2010; 2015). Santa Clara Valley Water also follows this approach (SCVWD 2013). This allows MWDSC and SCVWD to statistically include drought periods more extreme than experienced historically in its water supply reliability estimates. This is probably the most sophisticated routine representation of hydrologic variability in water supply reliability analysis by a California water agency.

*Statistically synthesized streamflows* – Hydrologic records are often short and under-represent the range of extreme events that water supply systems need to be prepared for. A large literature exists on statistical methods that use local and regional hydrologic observations to develop and calibrate stochastic models for generating large ensembles of long statistically representative scenarios of streamflows or other hydrologic conditions (Tasker and Dunne 1997; Hirsch 1979; Lamontagne 2017).
Broad range of scenarios – Another approach to representing a broader range of hydrologic scenarios than have been experienced historically is to rely on a broader but less statistically careful range of hydrologic events, potentially generated by various means. MWDSC also uses this approach, which has value for stress testing system operations under a wide range of plausible, but not statistically representative, conditions (Herman et al. 2016; MWDSC 2010).

Hydrologic forecasts – Forecast inflows using a combination of NWS, CNRFC, DWR, and other forecasts, and modified historical streamflows are commonly used by local, state, and federal water projects for near-term and seasonal operational reliability analyses. “Position analysis” or similar “spaghetti curve” analyses are commonly fed hydrologically with such inflows (Hirsch 1978; Tasker and Dunne 1997; DWR Bulletin 120, FitzHugh 2016).

Four approaches have been taken to represent changes in future climate in water supply reliability studies:

Paleohydrology – Several studies have employed representations of severe, prolonged distant past droughts for water supply reliability analysis (Harou et al. 2010a; Woodhouse and Lukas 2006). These paleorecords are usually based on tree-ring studies or records of distant past lake levels and sediments (Adams et al. 2015; Meko et al. 2001; Stine 1994).

Climate model precipitation and runoff – Sometimes hydrologic inflows for water supply analyses are taken from one or more pairs of climate change and hydrologic models. This process will introduce several sources of uncertainty: a) from the selection of global circulation models, b) from the selection of greenhouse gas emission scenarios, c) from the bias correction method used in post-processing global climate model results, d) from selection and implementation of the downscaling method used to take coarser climate model results to finer scales needed for water resource studies, e) from the selection and use of the hydrologic, snowmelt, and groundwater models needed to develop streamflows and aquifer inflows from precipitation, temperature, and other climate conditions. These methods are often resource-intensive and can produce considerable and compounded uncertainties which are rarely explored (Mehta et al. 2013; Joyce et al. 2011).

Climate change adjusted historical inflows – Adjusting historical inflows are commonly adjusted to match statistical differences with climate change hydrologic outputs from paired climate change and hydrologic models, usually representing changes in seasonal shifts in flow means and variance. This approach better preserves observed spatial and temporal auto-correlations in streamflows and
experienced hydrologic persistence in extremes, but also can be limiting in these regards (Zhu et al, 2005; Willis et al. 2011; DWR 2018b, 2019).

Continuous adjustment of historical flows – To represent the likely future evolution of streamflows or conditions with climate change, so authors have represented climate change as a continuous change in the mean and standard deviation of historical conditions or streamflows (Hui et al 2018). This can efficiently summarize the effects of climate change without more awkward and computationally burdensome use of an ensemble of GCM and derivative results.

Parametric climate representation- Because climate change is uncertain, it can be insightful to represent major aspects of climate in a few parameters, and then systematically change these parameter values to assess the vulnerability and responses of the water system under a range of conditions. Several such studies for water supply systems have been done in California (Kiparsky et al. 2014; Willis et al. 2011). A more systematic version of this approach, sometimes called “Decision-scaling” where the performance of particular decisions is assessed to identify the scale of changes under which a system or decision performs well (Brown et al. 2012; Albano et al. 2021; DWR 2018b, 2019). This is essentially an inverse-scenario approach that requires generating fewer, but smarter, scenarios to assess system performance.

The representation of potential climate changes into the future has usually been as a single climate change scenario, fixed weighted multiple climate change scenarios, or multiple scenarios with Bayesian updating of their probabilities. Of these, the examination of a single scenario has been most common, and has shown many consistent impacts and insights for policy and management. Recently, reliability results for multiple scenarios have become more common, and better shows where and how reliability results and policies might diverge with future climate.

Over time, observations of changes in climate might narrow the scattering of potential climate futures produced today, and could help in updating water management plans, infrastructure decisions, and policies. Two recent papers have examined the use of Bayes’ Theorem to update probabilities of climate scenarios for the future based on future climate observations, and integrated these calculations into reliability optimization studies for long-term water infrastructure (Fletcher et al. 2019; Hui et al. 2018).
Representing Human Water Demands

Representing humans and their water use decisions is an important aspect of water supply reliability estimations (Madani and Shafiee-Jood 2020). Several approaches are summarized in Table 8 and discussed below.

Table 8. Approaches to Representing Human Water Demands for Water Supply Reliability Studies

<table>
<thead>
<tr>
<th>Approach</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Delivery targets</td>
<td>Fixed desired water deliver volumes, often varying in time</td>
</tr>
<tr>
<td>Water demand curves</td>
<td>Economic values of delivered water, often varying in time to better represent variable values of water delivery</td>
</tr>
<tr>
<td>Uncertainties in water demands</td>
<td>Probabilistic or multiple scenario variations on water delivery targets or economic values of delivered water</td>
</tr>
<tr>
<td>Climate change and water demands</td>
<td>Modifications of water delivery targets or economic values for changed climate conditions</td>
</tr>
</tbody>
</table>

Delivery targets – Classically, water supply reliability analyses represent water demands as target delivery quantities. These will often vary by month (and sometimes by smaller time-steps) and sometimes vary by year-type (dry versus wetter years). Small and large failure to be able to provide these target deliveries are all counted as equally unreliable.

Water demand curves – However, because different amounts of water shortage incur different levels of economic or other losses, economists and engineers have long suggested the use of economic demand curves (Dupuit 1853; Howe and Smith 1994; Harou et al. 2009). Water demand curves often vary seasonally (sometimes with time of day and sometimes by year-type). In modeling, they are often recast as penalty functions with growing amounts of shortage resulting in growing amounts of economic losses.

Uncertainties in water demands – Most representations of water demands in water supply reliability analyses are fixed deterministic. However, particularly in planning time frames, water demands often have considerable uncertainty. Sometimes these uncertainties are represented as an ensemble of equally-probable water delivery targets, or potentially as an ensemble of equally-probable water demand curves. San Diego County Water Authority has taken this approach in planning (Kiefer and Porter 2000).
Climate Change and Water Demands – Climate change will affect water demands as well as water availability, particularly for agriculture. Higher temperatures increase evaporation and evapotranspiration rates, and will lengthen growing seasons in some areas, increasing water use, but also decrease the time needed for crops to mature, potentially decreasing irrigation water demands. Higher carbon dioxide concentrations also are likely to affect crop maturity, yields, and selection (Pathak and Stoddard 2018; Pathak et al. 2018; Lee et al. 2011; Lobell et al. 2007).

Representing Time

Static Future Conditions – Most water supply analyses estimate reliability for a particular slice of time, present or future, usually representing water demands expected for a specified time in the future. So it is common for studies estimating reliability for estimated 2020, 2040, 2050, or 2100 conditions, often referred as a future “level of development.” The system simulation model then examines these estimated future conditions using historical or other hydrologies to estimate the probability distributions of water deliveries for these future conditions.

Continuous simulation – A more elaborate and time-consuming representation of time for water supply reliability estimation estimates reliability in each year from the present into the future. This is done by running a system simulation model many times using randomly estimated hydrologic and water demand conditions, including how these conditions are thought to change into the future. This requires characterizing the randomness in hydrology/climate, water demands, and other important reliability factors, and how this randomness changes with time. This approach is essentially the “plotting position” approach common for seasonal water supply reliability analysis, applied to longer-term planning (Hirsch 1978). These results become harder to generate and explain, and can introduce new spurious sources of error. The Bayesian approached described above are a more sophisticated form of continuous modeling (simulation or optimization) (Fletcher et al. 2019; Hui et al. 2018).

Representing Decision-making

System modeling for water supply reliability also requires representation of operational decisions over the course of hydrologic events. These include reservoir releases, implementation of drought water conservation actions, changes in crop mix, groundwater recharge, and other decisions that affect the portfolio of management activities available for the water system. Because these operating decisions usually vary each year with hydrologic, water demand, and other conditions, some representation of decision-making must be included in system models. Several approaches are common.
Some models represent operating decisions during their simulations with a series of rules, representing established or expected policies for operating each element of water supply and demand management portfolios represented in the model over the range of hydrologic and other conditions. Such fixed operating rules could include reservoir releases as a function of water stored in the reservoir, groundwater pumping as a function of the difference between water demands and surface water availability, or the implementation of water conservation actions based on the amount of water stored in reservoirs. Although there is a vast and insightful literature on water system operating rules (Macian-Sorribes and Pulido-Velazques 2019), such rules can prove inflexible and difficult to adapt to new conditions, such as climate change.

More recent water supply simulation models embed an optimization algorithm that makes such operational decisions based on prioritized technical objectives, such as implementation of seniority-based water rights, within capacity, water availability, and other constraints. This approach is much more flexible and adaptable, and usually easier to implement in software, than direct rule-based simulations. CALSIM, WEAP, and many other contemporary water system simulation models take this priority optimization approach, which is usually implemented for each time-step individually (including New York City's Operation Support Tool (NASEM 2018, using OASIS software) and ModSIM (CSU 2017).

A third approach to representing decision-making is explicit optimization of fundamental objectives, within constraints. Some such models minimize overall economic costs (or maximize overall economic value) within other physical and policy constraints. Optimization-based operations are the most flexible and adaptable operations for scenarios which diverge from current operating experiences, but can be over-optimistic in terms of actual decisions made (Harou et al. 2009; Tanaka et al. 2006).

A fourth approach, sometimes used in decision-making exercises, is to have actual or surrogate human decision-makers make decisions during each time step, or at crucial time-steps (say, during drought). This can help decision-makers think through decisions in a simulated context. Although this is perhaps the most adaptable way to represent decision-making in system models, model run-times are much slower when humans must make decisions, greatly restricting the range of conditions which can be examined in this way. It is also possible, and perhaps likely, that human decision-makers would make different decisions if presented with the same conditions a second time, perhaps reducing the replicability and transparency of the modeling results. Although this approach is rarely used, and
even more rarely documented, it can be useful for integrating modeling and decision-making.

Sometimes hybrid approaches are used to represent decision-making. There is no perfect representation of decision-making in system modeling.
Appendix B. Questionnaire Responses and Interviews

To help inform its review of water supply reliability estimation (see prospectus) the Delta ISB released a questionnaire to survey applications and issues with water supply reliability estimation and to develop an inventory of water supply reliability estimation efforts. The board also conducted a series of 30-minute interviews with multiple practitioners of water supply reliability estimation.

Responses to the questionnaire that were received through January 25, 2019, are compiled and analyzed in appendix sections, B.1 and B.2. Section B.1 is a summary of data from completed questionnaires. The section consists of two parts. Part 1 lists the organizations of the individuals who responded to the questionnaire and compiles responses to questions about applications of and issues with water supply reliability estimation. Part 2 inventories water supply reliability estimation efforts. Section B.2 presents an analysis of the responses in Section B.1. It includes discussions of potential bias in the responses to the questions caused by the small sample size.

Section B.3 summarizes responses to interviews conducted after the workshop on September 13, 2019, by Delta ISB members with a diverse variety of practitioners. Interviewees were asked the same set of questions and responses are compiled without attribution.

Section B.1 - Data Summary

Twenty-two individuals responded to the questionnaire from a range of organizations:

- Berkeley National Laboratory
- California Department of Water Resources (DWR; N=3)
- Central Delta Water Agency
- California Water Research
- East Bay Municipal Utility District
- GEI Consultants
- Metropolitan Water District of Southern California
Individuals were not asked to respond on behalf of their organizations. The respondent's length of involvement with water supply reliability estimation is documented in the figure below.

All responses are included, and no edits were made to the responses.

1. In general, are water supply reliability estimates and studies done in a rigorous technical way (N=17)?
<table>

20. Integrating regional or statewide data into a trend analysis for the basins supplying a particular water agency is a broad-brush approach but probably suitable for a 20-40- or 60-year planning horizon.

21. More detail needed as is being developed in CVHM-2

22. There have been some significant recent improvements in analysis of shifts in hydrology due to climate change and drought impacts. But the lack of validation of the CALSIM modeling of reservoir operations remains a major issue for all reliability studies with the model. Calibration data and error estimates for the model are also unavailable. The impacts of high sea level rise due to accelerated disintegration of the polar ice sheets have also not been considered and will have major impacts on the SWP and CVP.

2. In general, are reliability estimates sufficiently understood, communicated to, and applied by managers and decision-makers (N=17)?

<tr>
<td>20</td>
<td>Typically water agencies react by planning to expand storage or sharing rights to storage of making connections to adjacent basins. This addresses short-term impacts. A more useful approach, in the face of climate change, would be to enhance local groundwater management and plan and build for recycling for non-potable and potable use. If managers really believe the population growth numbers they put in their 5-year plans, they should plan how to reduce per capita demand. This would include tiered water rates (say 10 steps, each one with a rate X% higher than the rate for the tier below), no fixed charge, develop customer expectations that rates will rise each year. As population grows, if population grows, rates will rise to keep demand in the bounds of reliable supply. Strict adherence to development limit lines will keep the value of land in the service area high. People won't be building houses that take up a lot of land for irrigated lawns. Land will be used for dense housing, efficient employment and politely shared green spaces. Tiered rates for residences might be set at a tier size of 1 CCF per month per resident. Commercial and institutional rates might be set based on a tier size of 0.35 CCF per FTE employee or student. Rates for non-potable water would be lower - for irrigation use - making shared green spaces affordable.</td>
<td>Somewhat</td>
</tr>
<tr>
<td>21</td>
<td>Need to broaden the analysis of drivers that could affect water-supply reliability such as climate change, land subsidence, saline-water intrusion of Delta, and tunnel projects.</td>
<td>Somewhat</td>
</tr>
</tbody>
</table>
4. What major technical and application problems and uncertainties do you see in water supply reliability estimation that limit their utility for management and decision-making?

<table>
<thead>
<tr>
<th>Respondent #</th>
<th>Response</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>Non-standardized or absent documentation and reporting of model inputs; lack of explicit model testing and error analysis</td>
</tr>
</tbody>
</table>
| 2            | Technical/application:  
  - information availability  
  - coordination/communication  
  - transparency  
  - Buy-in. I mean real buy-in, where entities are not just going through the motions, but have some real commitment to the outcome and to making clear progress. |
<p>| 3            | Lack of consistent approach, lack of open and accessible data, lack of trust in data and methods among stakeholders |
| 5            | Increased frequency of catastrophic events creates a new &quot;normal&quot; and can throw off reliability estimation activities. |
| 6            | Raw input variable access, including mountain wilderness areas; data sharing between a multitude of users and forecasters. |
| 7            | Water supply reliability estimates are used for different purposes with different assumptions. Communicating those assumptions/purposes of the different applications would help in understanding the larger picture. This workshop hopefully will provide a way to do that. It doesn't necessarily mean that one method is wrong or better than another. It depends on the application. Additionally some of the agreements or legal requirements for reliability estimates do not include Climate change or Paleo data. That data/information will provide additional uncertainties in reliability estimation. The difficulty is in how to bracket that uncertainty for near and longer term decisions. |</p>
<table>
<thead>
<tr>
<th>Respondent #</th>
<th>Response</th>
</tr>
</thead>
</table>
| 9           | 1. Clear and succinct communication of complex results to a diverse audience.  
              2. Data uncertainties due to unknowns related to climate change, population growth, environmental regulations, and future innovations.  
              3. Determining commonly agreed upon metrics that identify potential future water supply shortages |
<p>| 13          | Reliability depends a lot on operational decisions and demand estimation. Further standardization of model operations decision envelope and levels of demand met (changing effects with increasing shortage) would contribute to analytical consistency (and not just decisions that suit USBR or DWR). |
| 14          | Modeling results presented to the SWRCB and other State agencies only analyze impacts to CVP/SWP water exporters and fail to analyze degradation of water quality for in-Delta water users/diversions or determine whether compliance with water rights contracts such as the NDWA 1981 Contract can be maintained under existing CVP/SWP operations or expansion of SWP with construction of WaterFix intakes and tunnels. D-1641 is only April thru August 15th and therefore is not relevant to year-round salinity criteria contained in the 1981 NDWA-DWR Contract. |
| 15          | While there are some good estimates of the potential water supply for a given month or a year, net water use in cities and agriculture is often a big unknown. This makes it difficult to properly plan and reconfigure system operations especially during droughts. |
| 16          | Climate change and population growth |</p>
<table>
<thead>
<tr>
<th>Respondent #</th>
<th>Response</th>
</tr>
</thead>
<tbody>
<tr>
<td>17</td>
<td>I will provide a list of about six that I came up with in preparation for the workshop: (1) Climate change and non-stationarity of hydrologic distribution where the hydrology of the past is less reliable for representing hydrology of the future; (2) Regulatory uncertainty such as SWRCB curtailments that were a feature of the recent drought that are inherently unpredictable; (3) Policy &quot;off-ramps&quot; such as public health and safety and unanticipated yet legally valid deviations from defined policies; (4) Scenario management can become a problem with so many components to the process where the number of scenarios or alternatives can easily grow large resulting in making decisions more difficult and/or finding common ground between disparate views more of a challenge; (5) Compounded uncertainty where there can, again, be several components to the analysis where information from the different sources can be correlated or synergistic; (6) Variability in risk tolerance either because of changes in circumstance over time or as a function of changes in decision makers or agency objectives in the short or long term.</td>
</tr>
<tr>
<td>18</td>
<td>Not as useful for project-specific analysis. sometimes not enough detail (nodes)</td>
</tr>
<tr>
<td>19</td>
<td>People need to understand that CalSim and other models are used for comparative purposes to generally evaluate the differences between proposals and may not be effective for real time evaluation.</td>
</tr>
</tbody>
</table>
Supply reliability is challenged by seasonal variations (in which month will it rain?), by cyclical fluctuation based on our less than 150 year window of history, political transformation as we see the human impact on the water cycles at and below the ground level, political transformation as we react to the impact of climate change on the evaporation-transpiration-precipitation cycles over every region and every basin. The failure of political animals - Future Farmers of America, voters, politicians and scientists to think long means that we are usually working today to solve yesterday's problem, not tomorrow's. We need to make sure we are ready to do more with less - water.

Future changes in land use and climate change.

Interannual water supply reliability is closely tied to reservoir operations. Reservoir operations are changed regularly in ways which are non-transparent, and may not be optimal for all beneficial uses. River reaches often have significant losses to groundwater in critically dry years or extended droughts, which may not be reflected in hydrologic models based on average flows.

5. What are some major technical or institutional innovations that would improve the use of water supply reliability studies in the future?

<table>
<thead>
<tr>
<th>Respondent #</th>
<th>Response</th>
</tr>

<tbody>
<tr>
<td>1</td>
<td>Documentation expectation standards for models and applications</td>
</tr>
<tr>
<td>3</td>
<td>High resolution data that is federated. Open source models.</td>
</tr>
<tr>
<td>5</td>
<td>Better estimates of groundwater contribution to annual water supply. Modeling capability has lagged surface water modeling. Integrated models needed.</td>
</tr>
<tr>
<td>6</td>
<td>Funds and technical training, and ability to attend technical conferences, and opportunities for staff participation in technical discussions with researchers, sometimes out of state.</td>
</tr>
<tr>
<td>Respondent #</td>
<td>Response</td>
</tr>
<tr>
<td>-------------</td>
<td>----------</td>
</tr>
<tr>
<td>2</td>
<td>Technical</td>
</tr>
<tr>
<td></td>
<td>• higher resolution data (spatially and temporally) so that water use studies could directly address demand and use, both critical elements in determining reliability.</td>
</tr>
<tr>
<td></td>
<td>• data management and visualization tools - both on the front and back end of analyses. This would allow better understanding and quality control of data (front end), as well as interpreting output and analysis results, and ease conveying approaches and results to managers and decision makers</td>
</tr>
<tr>
<td></td>
<td>Institutional</td>
</tr>
<tr>
<td></td>
<td>is this a trap? There are so many points here. Coordination among and within institutions is a huge challenge. Funding is likewise a constraint for institutions. There is also a tendency for institutions and institutional processes to lack flexibility, to be nimble, and to evolve - not all institutions, but these elements are common. This is kind of vanilla pudding and probably not much help. However, developing and maintaining in-house expertise is remarkably effective when and where it happens</td>
</tr>
<tr>
<td>7</td>
<td>Hard to say. Continued improvement in data and modeling studies. Better communication. Ways to present uncertainty or ranges of estimates that are understandable to managers. Normally it is difficult to get beyond a &quot;one answer&quot; approach for decision makers.</td>
</tr>
<tr>
<td>8</td>
<td>Opportunities for reservoir reoperation in conjunction with ground water recharge methodologies can stabilize the supply/demand equation</td>
</tr>
<tr>
<td>Respondent #</td>
<td>Response</td>
</tr>
<tr>
<td>-------------</td>
<td>----------</td>
</tr>
</tbody>
</table>
| 9           | 1. Improved certainty of the local climate model projections for precipitation timing, precipitation volume, and temperature.  
   2. Improved understanding of how different types of water supply projects may help (or not help) with climate change.  
   3. Improved approaches for water demand modeling  
   4. Improved communication and/or collaboration across agencies (i.e., through institutional support and funding for Integrated Regional Water Management) |
| 11          | Common sense!!!! Also, political agendas and egos often override technical information |
| 13          | 1. Standardization of demands and operations as above,  
   2. Development of the language/vernacular of major reliability dynamics and causal relationships, and  
   3. Further examples of "objective" basin wide analysis or a trusted entity to conduct unbiased analysis that can withstand cross-examination in evidentiary proceedings. |
<p>| 14          | Independent modeling conducted separate from the one-sided SWP/CVP affects conducted by DWR/USBR is necessary to show the impacts to the other hundreds of smaller agricultural diversion pipes in the Delta (25 cfs and less) that pre-exist the CVP and SWP water rights. |
| 15          | A coherent and standardized water accounting system, that identifies major elements in regional water balance, and uncertainties. In the case of agriculture, a comprehensive land use survey program would also be beneficial. |
| 16          | Accessibility of models to a broader water community. |
| 17          | Big data analysis methods such as machine learning that may be helpful in identifying important patterns in large data sets that ultimately may reduce uncertainty or improve precision of demand estimates or consumption patterns. Building in flexibility into existing or proposed/future regulations. Perhaps obvious would be improving both short term and long term forecasting to reduce water supply uncertainty inter- and intra-annually. |</p>

<td>Response</td>
</tr>
<tr>
<td>--------------</td>
<td>----------</td>
</tr>
<tr>
<td>6</td>
<td>New and simpler remote measuring devices or tools, possibly from space via satellites; better long range weather forecasting.</td>
</tr>
<tr>
<td>7</td>
<td>Improved data, data management, transparency of data. Continued development of better hydrologic, water system, and Climate modeling. Ways to manage to a range of uncertainty.</td>
</tr>
<tr>
<td>8</td>
<td>See response to question 5</td>
</tr>
</tbody>
</table>
| 9            | 1. Research on water conservation technologies and effectiveness  
2. Research on how to improve community water conservation  
3. Research on maximizing stormwater capture and recharge in a Mediterranean climate  
4. Research on how and to what extent new water supply technologies may help with adapting to climate change  
5. Research on emerging water supply technologies and an assessment of their potential for meeting future demands |
<p>| 13           | There are glaring gaps in existing streamflow data collection networks, and for temperature. Construction of next-generation basin wide models with common-assumptions frameworks for LOD/demand and operational prioritization could help. |
| 14           | DWR modeling on WaterFix, drought plans presented to SWRCB, and others venues only analyzes water supply impacts to CVP/SWP water contractors and ignores water supply and quality impacts to in-Delta water users. Independent modeling is necessary to provide more comprehensive impacts to other water users besides SWP/CVP water contractors. Research should also determine the amount of water that is used, excess put back into the rivers and then re-used downstream in order to get a better handle on consumptive use in watersheds. In other words, the amount of diverted is not the same as the final amount used because a portion is put back into the rivers/channels. |</p>
<table>
<thead>
<tr>
<th>Respondent #</th>

<td>We can't really manage water supply, we can only manage water use.</td>
</tr>
<tr>
<td>21</td>
<td>Better estimates of land use and application of water for agriculture as well as better estimates of climate change with 6-month to one-year forecasts could help refine operational decisions.</td>
</tr>
</tbody>
</table>
### B.1. Part 2: Inventory of Water Supply Reliability Estimation Efforts

The table below is an inventory of water supply reliability estimation efforts in California. The inventory was compiled based on what was provided in the questionnaire responses with limited modifications. The order of the inventory is based on the alphabetical order of the group conducting or employing the estimation efforts. It does not correspond to respondent number in Part 1 of Section B.1. Because of the amount of information presented, the State Water Resources Control Board's inventory information is presented as a fact sheet (see end of table) and is not in the table below.

State Water Resources Control Board
Division of Water Rights

Purpose Underlying Estimates

The State Water Resources Control Board and 9 Regional Water Quality Control Boards (Water Boards) are tasked with protecting the quality of California's water resources and drinking water for the protection of the environment, public health, and all beneficial uses, including public trust uses. The Water Boards are also tasked with administering the State's water rights system. In doing this work, the Water Boards employ water supply reliability estimates when: developing and implementing regulatory requirements related to flows, including in flow dependent water quality control plans like the Bay-Delta Plan and associated environmental analyses; in determining water availability for new water rights; in determining when water is not available for diversion during times of shortage; and in the regulation of drinking water systems.

Water supply reliability estimates are specifically used by Water Boards staff in updating the Bay-Delta Plan to understand the range of potential effects from changes in flows and flow dependent water quality requirements. The Board considers the benefits of proposed regulations and the water supply costs when it makes decisions regarding the reasonable protection of all beneficial uses.

When making decisions about whether to grant new water rights, the Water Boards also consider water supply reliability in determining whether to grant new water rights, the season of diversion, and other conditions. During times of water scarcity, the Water Board must also determine when water is not available for water users based on their water right priority. While these analyses do not incorporate water supply reliability explicitly, they do incorporate the same information; water supply estimates and demand estimates.

Water supply reliability is generally defined as the fraction of time that a specified level of demand can be met. Water supply reliability depends on available supply, demand, and reservoir management choices that are based on the risks and rewards of short-term and future use. Typically, water users make decisions based on these factors in how to allocate water use to meet demands. In planning scenarios, Water Board staff are tasked to develop sufficiently accurate representations of baseline water use patterns and operational decisions in order to evaluate likely changes in reliability for certain policy alternatives. This reliability manifests in fractions of baseline water demand that can be met for municipal,
agricultural, and fish & wildlife beneficial uses, and subsequent potential economic and environmental impacts.

Reservoirs improve reliability for consumptive uses by storing natural supply that exceeds demand for use later in the season or in future years. Reservoir operators balance the need to release water from the reservoir to fulfill seasonal water demand with the need to retain water in the reservoir to be available for future demand, considering the uncertainty of future inflows and the risk of drought. Multiple, successive dry years present difficult choices between releasing reservoir water to meet a portion of immediate demand or storing reservoir water for a future year with the risk of additional shortage. The Water Board's authority primarily affects users' available supply through conditions on the exercise of water rights, while reservoir operational decisions and demand management are typically controlled by water users.

Water supply reliability is also a consideration in the regulation of drinking water systems, including decisions about regulatory requirements that are needed to protect public health and ensure the efficient use of water resources.

**Frequency Estimates are Updated**

Time periods for the above water supply estimates vary based on the circumstances. For the Bay-Delta Plan they coincide with the planning cycles which can be from 3 to 10 years. For water right applications they occur once per application. During times of drought, for short term planning and enforcement purposes, water supply estimates are employed monthly or more frequently.

**Computer Models or Modeling Groups Used**

In Bay-Delta planning, the Water Supply Effects (WSE) model (based on the CALSIM II water balance framework) was used for the San Joaquin update of the Bay-Delta Plan, and the Sacramento Water Allocation Model (SacWAM), an application of the WEAP model (see below), is being used for the Sacramento/Delta update of the Bay-Delta Plan. For water supply shortage analyses spreadsheet models have been employed.

Response 3.2 for documentation and details of modeling approach and responses to frequent comments)

- Sacramento/Delta Update of the Bay-Delta Plan: Framework Document (See section 3.3): SacWAM Website
- State Water Board: Drought Year Watershed Analysis
- Drought Water Right Curtailment and Analysis Tool (DWRAT)

**Application of Estimates**

They are applied in regulatory and planning processes as discussed above. Historically, the State Water Board has relied on other organizations such as USGS, NOAA and DWR to produce real-time and historical water supply estimates. These estimates of streamflow forecasts (e.g. DWR Bulletin 120 and Water Supply Indices) and unimpaired flow (DWR 2016) are used to inform instream flow requirements and water quality objectives.

**Best Use of Estimates**

The uses of water supply reliability estimates depend upon the context in which they are being applied. They can be used for planning or regulatory purposes. For planning purposes, they are best used in a comparative sense. (e.g., WSE and SacWAM).

**Section B.2 - Analysis of Responses**

This section analyzes the 22 responses to the questionnaire that were completed in conjunction with the January 10, 2019, Delta ISB Workshop on Water Supply Reliability Estimation. Respondents from State and Federal agencies, local agencies, and consulting organizations dominated the responses with 6 in each of the three categories. Only 4 individuals, two each, respectively, responded from academic and nongovernmental institutions. The respondents were an experienced cadre, with 12 of the 22 having 10 or more years involvement in the field. The names of the organizations represented by the respondents are listed in Section B.1. The analysis here compiles and identifies general trends. Because of the small sample size and professional diversity of responders, potential bias in the response are evaluated particularly for the first three questions. The reader is referred to Appendix B.1 for individual comments numbered in order of their submittal. The Appendix does not identify responders, but their identity was used for the analysis of potential bias in Section B.2.
Question 1: In general, are water-supply reliability studies done in a rigorous technical way?

Seventeen of the 22 respondents answered this question. The bottom line is that 59% of the respondents did not answer yes with most (50%) of the respondents answering somewhat. Evaluation of potential bias: Of the 17 respondents, 5 were consultants and 6 represented government agencies. Four of the 5 consultants and three of the 6 government employees answered somewhat or no, which is probably not a significant difference. Thus, the 59% based on all 17 respondents seems to reflect the opinions of engineers on the front line.

Written responses: The negative tone of the overall response is reflected in the comments. Absence of standards, need for competence and judgement in model operation, and inadequate estimates of uncertainty were the most common comments.

Question 2: In general, are reliability estimates sufficiently understood, communicated to, and applied by managers and decisionmakers?

Seventeen of the 22 respondents answered this question, but the 17 respondents did not completely overlap with those answering question 1. The bottom line is that 73% of the respondents did not answer yes. Evaluation of potential bias: Of the 17 respondents, 5 were consultants and 8 represented government agencies. All 5 consultants and 4 of the 8 government employees answered somewhat or no. Thus, the 73% overall response roughly reflects the opinions of engineers on the front line although there may be a difference of opinion between consultants and employees of government agencies, with the consultants being more skeptical.

Written Responses: Lack of understanding and the communication challenge were overwhelmingly cited as the basis for the negative tone of the overall response. Standardization and decreased bias were proposed as partial solutions.

Question 3: In general, are water supply reliability estimates and studies employed in policy and management discussions and decisions?

Seventeen of the 22 respondents answered this question, but as noted previously, the respondents do not completely overlap with respondents in questions 1 and 2. The bottom line is that 50% of the respondents answered yes with an additional 36% answering somewhat. This yields 86% with a positive response. Only 5% answered no. Evaluation of potential bias: Of the 17 respondents, only 3 were consultants and 7 represented government agencies. Two of the 3 consultants answered somewhat with third not expressing an opinion. Six of the 7 responders
from government agencies answered yes. Thus, the 86% overall response roughly reflects the opinions of consultants and engineers on the front line.

*Written Responses:* Despite the positive tone of the responses, there seemed to be some detachment from technical findings and the application or decision-making process; both parties are not in the room together.

**Question 4:** What major technical and application problems and uncertainties do you see in water supply reliability estimation that limit their utility for management and decision-making?

Climate change was the most cited limitation by the 17 respondents, being referenced 7 times. Standardization and transparency were also cited, but less frequently. There were a few references to uncertainty and they included both input data and regulatory uncertainty. A potential bias caused by sampling was not evaluated because individual respondents commonly identified multiple limiting factors. Thirteen of the respondents were either consultants or employees of government agencies.

**Question 5:** What are some major technical or institutional innovations that would improve the use of water supply reliability studies in the future?

This question produced a variety of suggestions by 18 respondents. Innovations mentioned by multiple respondents included:

- Standards
- Inclusion of groundwater
- Improved models with more transparency, and
- Acquisition of hi-resolution data.

**Question 6:** Science needs. What are some research directions that might support improvements in water supply reliability estimate and use of such estimates for management and decision-making?

A variety of scientific research directions were proposed by the 18 respondents. Data was the only theme that stood out, being mentioned by 5 respondents. It included a range of aspects including improved data collection, management and transparency, and uncertainty analyses. Other directions mentioned two or more times included:

- How to incorporate groundwater resources in models
- Water conservation
• Better estimates of uncertainty, and
• Accounting for climate change.

Question 7: Other comments or suggestions on water supply reliability estimation.

Only 7 respondents contributed to this section. Two of the respondents commented on the wide range of application of models for water supply reliability estimation and one of these recommended that experts provide a framework that is applicable at all scales. Better management of water use (conservation), documentation of land use, prediction of climate change, and inclusion of water quality were all referenced.

Inventory of water supply reliability estimation efforts

Nineteen respondents completed the inventory of purpose, frequency of estimates, and application of water supply reliability estimates. Only the purpose of the estimation effort and frequency are compiled here.

The predominant (11 respondents) purpose of most efforts is to support planning or policy development. Only 3 respondents mentioned that they were used directly for delivery decisions.

The frequency of updates is dominated (11 respondents) by annual or longer (typically 5 years) time periods. Three respondents indicated updates were performed monthly or weekly.

Section B.3 - Interview Responses

As part of its information gathering process for this review, Delta ISB members conducted interviews with a broad spectrum of scientists and engineers engaged in water supply reliability estimation. This section summarizes comments and observations gleaned from those interviews. The comments and observations are not verbatim, but have been edited for clarity and terseness.

Interviewee selection criteria

Participants who were invited for 30-minute-long interviews were selected to reflect a variety of perspectives based on their experience with water supply reliability estimation and their employer. General categories of interviewees included State and federal regulators, regional and state water agencies, and consultants. Interviewees were informed that they would be identified as participants in the interview process, but that specific comments would not be attributed.
Interviewees and affiliations (alphabetical order):

Ben Bray, Ph.D., East Bay Municipal Utility District
Andy Draper, Ph.D., Stantec Consulting
Tina Leahy, State Water Resources Control Board
Scott Ligare, State Water Resources Control Board
Jennifer Nevills, Metropolitan Water District of Southern California
Nancy Parker, U.S. Bureau of Reclamation
Nicky Sandhu, Ph.D., Department of Water Resources
Robert Tull, Jacobs Engineering
Julie Zimmerman, Ph.D., The Nature Conservancy

Questions and Responses

All interviewees were asked the same questions during the course of their interviews. The following interview comments are paraphrased from automated transcripts and notes of interviewers. They are not sorted in alphabetical order by author.

1. How do you use water supply reliability estimation?

Used on a 15-year cycle to plan and manage utility water supply and to fulfill state mandated water management plans on an approximately 5-year cycle.

We use water resource reliability estimation for all sorts of resource simulation modeling, data management, and demand forecasting. It also is used to develop the state's mandated water management plan.

Large scale system models for the Delta, the Central Valley, and Southern California. These have looked at reservoir operations, stream flows, deliveries, and groundwater pumping. We look at scenarios under different regulatory conditions. There might be new facilities or re operation of existing facilities. There might be climate change scenarios. There might be scenarios based on future land use and population.

2. What are your major concerns with water supply reliability estimates? What shortcomings to water supply reliability estimates limit or affect their use by managers and decision-makers? How much of the problem is communication/understanding and how much is model deficiency? How can these concerns be addressed?
The more robust the methodology, the more challenging it is to communicate implications to decision makers. A limited number of scenarios that are risk based can be educational.

In California, annual variability is a major challenge. Droughts are stress tests for both plans and the water supply system itself.

The questions that come from the water policy makers are usually straightforward and simple. They want a number on which to base a decision. The big question is how do you communicate that? When we do that, there are a lot of assumptions that we make and a lot of things that we kind of gloss over. That is fine until the point comes where they actually apply that in some way that doesn't, doesn't match up to the assumptions we made.

It's not an integrative and integrated look at the whole system, but we do have counseling which is another part of our branch.

Upstream effects are in both the hydrology and institutional policies, regulatory policies, and environmental flows.

We tend to look at things in isolation and we tend to focus on the things that we understand and have data for. We really analyze those in great detail and tend to either ignore or dismiss the things that we really can't get our hands around because we don't have the ability to analyze.

The major concern is defining long-term reliability. We do a really good job at is looking at metropolitan supplies versus demands and the range of future conditions and defining future reliability under those of conditions. The limitations have more to do with the inputs including supply estimates from other agencies and for other water sources. Just maintaining existing supplies can be challenging, e.g., groundwater estimates have gone down.

Just to keep maintaining existing supplies and then to keep building new supplies on top is very challenging. In addition, water quality concerns and regulation changes can knock out entire supplies very abruptly. So that's a lot of effort for us is to assess risk in local supplies. We've also learned a lot about the transfer market (or the lack of a transfer market) that was a big piece of our portfolio.

It's really just kind of repeated exposure to get our management and board comfortable. They need to repeatedly see outputs and the tools. They used to be
really uncomfortable with exceedance curves, but we showed them enough times that they got comfortable with them.

Environmental water supply reliability is not adequately represented in analyses and policy discussions.

My major concern with water supply reliability estimates in the broad context of my long career doing nothing but river system modeling is that there's this ever increasing conflict over water supply in California. And that is coupled with an ever broadening range of stakeholder interest. There are more people that are more concerned about water supply reliability. From my perspective as a modeler, I see that there's intense scrutiny of model results and what seems to be more and more required is an intense need for personalized results of modeling.

From the modelers point of view, I believe that we work pretty diligently on ongoing updates and upgrades. The solutions to a lot of these needs are not fundamentally technically difficult. In California where I do most of my work these days, it's the size of the system and how complex it is that makes implementing solutions slow. Modeling hydrology to represent one small corner of a watershed is not a daunting task, but doing it at a scale that responds to the very picky specific question that every single person who's concerned about what is playing in California has over the entire state is a very big problem. My fundamental response to all this is we just need more people.

There is a dearth of skilled modelers. It's also a double edge sword. Not many of us (modelers) right now are taking the time to train people. This is a really big problem. People move around and nobody stays and does the same thing for more than five years anymore. The mobility challenge exists around the country. We're a lot more mobile as a society. It's not a unique problem to California or water resources in general by any stretch, but we need to either just keep training more people so that out of the hundred people that you train, maybe five actually stick around for the long term.

The other part of the question, how much of the problem is communication and how much is model deficiency, is really interesting. My answer is kind of the same as to the technical side of things. Understanding is a huge problem. Stakeholders sometimes propose solutions that are infeasible because they either don't understand how complicated the system is or they don't understand or don't trust the models that produced results that they don't agree with or they don't like. If people just understood the system and modeling better, then maybe that would
alleviate some problems with communication. Addressing this means more time and more people to do outreach and really reach into all of the communities of interest and stakeholder concern. We've talked about for years having monthly counseling appreciation days, where information about the model is pitched to perhaps a nontechnical audience or an environmental audience or something like that. It would be great, but again, there is only so much time. It's another area where having additional people would, would really help.

What are my major concerns about supply reliability? One of the difficult things is to actually express reliability. How do you take the results of a model and turn it into a number or several numbers to communicate in a report to managers? Impact assessment? Typically our models produce monthly water supply estimates over a range of water supply conditions or hydrologic conditions. Hydrologic conditions might be based on a cold start, or they might be based on historical conditions transformed to take into effect climate change. My main concern is how we quantify our model results, what should they be measured against? How do you take results and express them in a way that is meaningful to water managers? We need to think about how water agencies and irrigation districts react in the face of supply reductions during dry conditions rather than thinking of them staying at a fixed level.

When most people think about water supply reliability estimation, they tend to think of it as really focused on water supply for agriculture and for general human use. That gets to what I think is missing, which is really a broader definition and understanding of the concept of the ecosystem. When most people talk about water supply reliability, they're really thinking about one particular piece. And I think that we need to think more collectively about all uses for water.

We need to develop flow criteria for all streams and rivers in California based on the concept of functional flows. Try to come up with a way to define what's needed for nature, either to be broadly ecologically protective or defining first cut recommendations for specific management objectives, either ecological or to meet specific needs for species. That part hasn't been adequately incorporated into the water rely water reliability estimation. A lot of modeling just incorporates the regulatory requirements for the environmental policy and they're treated as constraints. Everything else is designed to meet contracts and supply. It's really difficult in any process to have flexibility for ecosystem purposes.

Water supply reliability estimates are typically single sided. They focus on human needs. We need a paradigm shifts so that we're thinking about it more holistically.
Regulatory constraints are a big part of it. We need to manage for an idea of ecological sustainability rather than avoiding jeopardy. And I think that's something that's really gotten us into, into problems in the past. When we model human needs, they tend to be synonymous with, with contracted amounts of water. There's no analysis of tradeoffs of different uses.

There's very little discussion of using conserved water for other purposes. We currently have a hardened demand for water. This pops up in negotiations all of the time including voluntary agreement discussions and collaborative discussions about water management. There's this idea that there's a defined amount of water that's needed for human use and that can't be changed or shouldn't be changed. We need to take a step back to really look at what the tradeoffs should be. Another issue with current estimates is that we don't know how much water is needed to support ecological function.

The demand side is a really big piece that is often left out of the discussions because it's politically a difficult one to discuss.

My main concern is that models seem to sometimes or frequently overestimate reliability. What happens then is that in times of shortage, the environment is often the user that gets shorted. I think that way suppliers get away from better long term planning and being explicit about assumptions. It's both a communication and understanding problem. Sometimes it's model deficiency. An example is water temperature planning during the drought.

In the grand scheme of things, e.g., a statewide water project like CVP operations, it is more assumptions that go into a model before we enter drought, i.e., water that was allocated before the drought. It is a lack of carry over storage and long term planning for such a scenario. It's kind of a combination of all of those things. How can the concerns be addressed? It's a tough one because of the scale at which many of these decisions are made. It gets political and in a lot of these cases, there's a lot of short term gain that is weighed over long term planning.

There's a lot of pressure from contractors if they see declining reservoirs to increase their allocations. And you know where those pleas go, all the way up to the upper echelon of government. Then the pressure comes back down to increase the allocations where we really need to be thinking on a much longer scale than. Contractors are just thinking one year where long term planning is what really needs to happen. It's difficult to identify the best way to get there. One way to do it would be to impose additional regulations and requirements within water rights
that require certain carryover storage levels for major droughts because it doesn't seem like in the past they have been able to do it properly.

Different groups have different models doing their own analysis separately, which can be useful by highlighting the range of results that can come out of these models. It illustrates how we should not rely on one number coming out of these models. Maybe that's the value we should expect from this modeling. There are reductions here and there's an increase here and this is the approximate range, these increases and decreases. We've been focused on the number. Instead, we need to be focused on what does this number mean and does this number make sense?

Having a common model might be a benefit, particularly if it is transparent and usable for most applications. I don't think that we have that yet.

3. Are you comfortable using water supply reliability estimates to develop portfolios that include surface water, groundwater, reuse, and demand management? How could these studies be improved?

Our approach is like that in the financial world, not to have all of our eggs in one basket. A portfolio, however, can be challenging to develop because components of a water supply involve more than traditional water supply sources. For example, conservation and recycled water are now important. Incorporating elasticity of water demand in planning for demand management also can be beneficial and needs to be included.

Modelers do what is asked of them, but they usually try to improve integration of various models as well as seek improvements in specific models and data.

There has to be some willingness on all sides to take a little bit of risk in terms of operating things to try to provide a, a greater overall benefit even though it may provide some are risk and need some assurances to any particular entity that is participating in. By drawing hard lines in terms of silos, it makes it much more difficult to do that. In the projects that we are doing, everybody talks about multi-benefit projects and how wonderful they are, but they're actually hard to implement. How can we release the water or leave the water in the river to provide flow benefits to habitat?

Groundwater is always a challenge. The capabilities are getting better. If we ever see a CalSim3 with better integrated surface water and groundwater modelling, I think that would be a benefit versus what we're doing now. There could be
improvement in terms of understanding the constraints that are associated with the complex relationships between North and South and different agencies relative to groundwater banking, how you move water around and the frequency of being able to move that water into storage and get it out when you need it. And I think more parties would be interested in participating in some of those projects if they better understood the constraints and potential benefits.

We have learned a lot on the local supply side. Some of the supplies that we thought were drought proof were not as drought proof as we thought. Recycling is easy to sell in droughts.

It's very difficult to estimate the demand responses during droughts and economic recessions and to include the likes of emergency declaration. We've been collecting data to try and better understand how demands come back or don't come back from those conditions. The behavioral aspect is really hard to capture, it is really hard to know how behavior will or won't persist beyond a drought or a recession.

You don't really put probabilities on the scenarios themselves. You put it on, for example, how many of the scenarios are vulnerable.

The portfolio approach is a no-brainer and should be considered in the environmental balance.

In terms of our sophistication and how we deal with that, portfolios reveal shortcomings and where there is resilience. You can develop portfolios which we would consider different strategies and they might see how components like groundwater recharge interact. The conjunctive use itself or from groundwater may be structural parts of the portfolio and reuse and water conservation nonstructural. Put all these kinds of elements into a portfolio and you can evaluate resilience and identify the promising portfolio. And that's the nice thing about looking at resilience is your, your less focused on coming up with a precise or accurate estimate of both climate change and adverse conditions. We know we're going to be wrong. We may be wrong by everything. That's the margin. So rather than trying to come up with the best projection of future water supplies and conditions, we just look at as a large range as possible of future conditions. We can look for portfolios that are resilient.

To incorporate resilience, I don't think you're really building anything. Well, you've got to build your management actions into the model. So there may be physical facilitates or maybe new facilities and maybe reoperation of existing facilities such as active groundwater management, you may be building in additional reviews.
They might, instead of assuming that title water coming off agricultural lands or wastewater discharges to the river system, you're going to recapture those and reuse and reuse that water. So that part is all that is big that's going to be built into our operational models. But that I think what differentiates it is how you treat results. You identify a threshold under which when the performance if exceeded, your system is broken down, it hasn't provided the surface water reliability that you want. Then you look at the number of times that model results exceed a certain threshold and you've run say hundreds of future possible conditions, under different scenarios of climate change, sea level rise, population, and land use. And what you're really looking at is a system that will have the smallest number of exceedance of those thresholds. So you're not saying anything about the likelihood of one. It just saying for all these possible scenarios, this particular portfolio of water management actions results in only exceeding my critical threshold, let's say at 25% shortage to an open moderation fee and only occurs one year in 94 years or, or one month in how many months. It's more how we interpret the model results.

A portfolio approach would be a big improvement. Conjunctively using ground water and surface water is important. SGMA will lessen the availability of groundwater and increase the demand for surface water which will further stress riverine ecosystems.

There is also two sides of it, supply and demand. Portfolios should include both. Sources should be considered holistically rather than managed separately. And I think demand should be considered holistically as well. That would give us a better sense of what the tradeoffs are between different types of uses and, and maybe encourage switching between sources as well. Without integration, you're just kind of addressing these separate needs in a vacuum.

We need to support the ability of water systems, which we between broadly defined as rivers and streams as well as human infrastructure, to support native biodiversity and ecosystems while meeting the needs of people. Part of that is to have an understanding of whether our water system can meet needs into the future under climate change scenarios. That includes periods of stress, such as drought and flood and, fire and additional regulatory actions. Are we considering all those things? Are we able to still meet a broad suite of needs? No way.

Maybe we're not inviting all the right people to be a part of the discussion. We focus a lot on the water users and the agencies, and a little bit on the NGOs. Water users are going to dominate the conversation. I think that's part of why we end up in the
same place most of the time, the same people who built the system to provide for human supply and to maximize are in charge. Those people have the strongest voice and it's not going to change because it's designed to meet their needs.

I think it would be really helpful if models were more holistic. Perhaps decision analysis where you have a structure and often a structure and collaborative process where you would build a model that can look at competing objectives. You can have more than one model and use them structure uncertainty in your view of the system. If we took that kind of approach, it, it would help a lot because then we would have models that would be built explicitly to meet the objectives of the group rather than just a water supply for human objectives.

4. Are environmental and ecological flows treated adequately by water supply reliability estimation? If not, how can environmental water reliability be better addressed?

In our own planning, environmental flows are paramount. We try to meet both flow and water quality requirements before any diversions can occur. If I put an academic hat on for just a minute, I understand the issue around the question: fish don't have water rights per se. Maybe California needs a steward like a Delta water master for environmental rights or for the entire system.

Anything we do going forward has tradeoffs and risk. In order to increase water supply reliability in terms of knowing that we are putting water to best use in terms of priorities relative to agriculture and the environment, we really need better information on those tradeoffs and risks. One of our, our biggest dilemmas is on the environmental side. We don't understand well enough from fisheries, ecosystems, and habitat standpoints what the water tradeoffs are in terms of trying to increase supply reliability to agriculture. At the same time we are trying to improve the environment. How do we strike the balance and how do we understand the risks to both sides in terms of changing operations with new projects?

Generally the challenging part of reliability estimation is on the habitat and ecosystem side. That is where it's very hard to identify the risk and to convince agents to participate in something a little more creative that might lead to a larger good and higher priority use of a block of water that they have available. They're just not geared to thinking that way. If they did, it's a different mindset versus a regulatory mindset or an impact mitigation mindset that they're used to dealing with. We have to move the whole discussion into a different arena in terms of what
agencies are allowed to do and, and how they can participate. I know that's all kind of a high level, but in terms of moving forward in a meaningful way to improve reliability and protect the environment and enhancing the environment, those are the sorts of things that really have to happen because the current regulatory structure and the current operational structure is just not conducive to that sort of support for multi-benefit projects that really could have a larger benefit if there was enough collaboration to put the pieces together and make it happen.

There's kind of two different questions here. Estimates reflect the current regulatory regime and demand for that water first and then they produce the estimates of supply that come after them. In the modeling, I think they treat those flows adequately. The other question, which is a different question, is are those existing flows adequate by themselves? I think that's a different question which I cannot answer. But as far as the modeling, yes, I think they had a mechanism to sort of account for those flows, if that makes sense.

Water supply reliability is a promising idea to encourage water suppliers to diversify. But the “dark side” is that it often means “how much can I extract as often as possible.” This perspective sees environmental water demand as antagonistic to the whole concept of water supply reliability.

Environmental regulations are needed to show that society values the environment – to make sure that water supply reliability is viewed holistically.

A daily model could certainly be appropriate for environmental. Environmental and ecological flows are challenging. We do have temperature models, habitat models, water quality, and salinity models, but the suite of modeling tools needs to be able to talk to each other. There are daily variability components that we can build into our monthly decisions, but for now, the lift that it would take to make this a daily tool is beyond possible. But that's just my personal opinion. Maybe the answer is that we build some kind of a daily operational tool that literally is used on a one-year basis.

So typically, system or management models have 30 calls times steps in one month. It just the first building block in a, in a heated analysis in which the upstream model provides information to a downstream model. The problem with our current analysis is with monthly times model times you are trying to say something about fishing fish survival. A colleague once noted that if you took the air out of the room you're in for 15 minutes, it would not be good for your survival. But if we average the air condition where you know the conditions on a monthly basis, there is no
problem. I think we have both temporal and spatial resolution issues in our temporal analysis. In our management models, we're not looking at what might be best for the environment. Where will we impose the current regulatory requirement? And there is, there is no sort of flexibility.

The Delta is a large portfolio. A huge portion of the portfolio for one user might be the only one for others. Keeping that in mind in the planning, framing some of the impacts within those portfolios is one way to help mitigate conflicts. That's different than what was done in the past. Portfolios of environmental management actions are a little bit more tricky. There may be multiple ways we can meet the same environmental goals. Whether it is habitat or flow, for example, we can acknowledge that there might be different ways to meet these same goals. And so potentially there could be this trade off. If a certain habitat is still there then, there could be a reduction in flows. They can meet the same objectives.

It is really difficult to model and to do it accurately. It's really important to have a discussion of climate change. With climate change and SGMA there is potential increased environmental flows. These will have a huge impact on the water supply available for diversion.

5. Is climate change treated adequately by water supply reliability estimation? If not, how can water supply reliability estimation address climate change?

Climate change is layered on top of a portfolio that includes many components and presents a complexity challenge for decision makers. We formerly used the droughts of historic record to build robustness into our planning, but it appears that is no longer adequate with climate change. Climate change is an area where the DISB water supply reliability review might add value by sharing how new methods approach this problem.

Hard to integrate changes in climate on decadal scale, with operations at a monthly level and water quality and flood responses on an hourly or shorter scales.

The first challenge is understanding what the climate change models are predicting, what is the range of variation in them, and why is that variation there?

If you look at climate change, which is one of the big driving factors for future water supply reliability estimation, models are coming. What is not clear to me is how those models and their assumptions play into what we are looking at. Because we are so far downstream in our modeling, we can certainly address certain issues of operations and how to do operations at a monthly timescale. But I believe the
longer time scales are really important to assess effects of climate change. The upstream effects are not understood in terms of what assumptions are in the models.

With things changing under future climate change conditions and different scenarios of the future may look like, I think it is going to be more and more important in terms of how do we do this. It is not just the water supply side, but also on the flood side, which is of course tied to water supply and groundwater management. We're just not structured to really facilitate, support and develop these multi-benefit projects. In terms of the way the agencies review things, they are focused on regulations. We need to step back from things and look at what is the best ways to use water and ask how do we get different agencies in water resources management to cooperate with environmental agencies and take a little bit of risk for the greater good.

Climate change is huge in terms of changes in precipitation, timing of runoff and sea level rise. We include a climate change component in everything we do these days and you're not sure exactly where things are going to go in the future. Some of the climate change estimates, especially on the flood side, are kind of extreme and we are trying to better understand what that really means. From water supply and ecosystem standpoints, water temperature management strategies are a practical concern. We have also looked at lots of different climate scenarios.

We pretty much work with the historical hydrology because that seems to be what folks are most comfortable with. We do look at design conditions in terms of the historical seven-year droughts in 1976 and 1977 and, and those sorts of things in terms of looking at the historical hydrology and, and extracting pieces of it. We have not gotten into a lot of stochastic stuff or Monte Carlo stuff. There just don't seem to be accepted although I personally think they are needed as we go forward. And understanding that simply looks at the last 82 years of our hydrology or a climate perturbed 82 years is not going to be adequate because there is uncertainty in the future and we need to take alternative approaches in terms of what is needed for design and, and planning and understanding, potential envelopes of future reliability relative to where things are going to be going. It's kind of amazing where we are now and kind of the traditional approaches we're still using and how hard it is to convince folks to move outside that and do things that are a little more unconventional. There seems to be a resistance there.
Is climate change treated adequately? I think not. We have a lot to learn about how climate change is impacting groundwater and surface water and how to incorporate it into our models.

Most people have one climate projection or one central tendency climate projection to work with. Trying to get people more comfortable with that space as multiple futures is a challenge. We have been doing this with portfolio planning since the early nineties.

Concerned that climate change is being used to ignore ecosystems.

We've been working with climate change scenarios for well over a decade in a variety of studies. There have been a number of climate scenario development efforts by different agencies too. All have used completely different perspectives to develop climate projections. What emissions scenarios? What future pathways and adaptation strategies might be in place? I think these are at least partially policy calls.

We already are challenged when we try to model extremes. Then you want to address impacts caused by climate change on water supply reliability. Over the last 10 years we've taken two approaches. We take downscaled results from a particular GCM model and apply that as one particular scenario or we take a different approach and use a collection of GCM's and downscaled results, which approximately tell the same story. We take groups of model results to represent different climate warmings or changes in precipitation. We're not only present water supply reliability for the natural hydrologic variation, but we're also saying this is the water supply reliability under different projections of the future. Those aren't disentangled very well when we look at water supply reliability, but we get from model the variability under changing climate conditions.

Climate change is a tough one. Addressing ecosystem needs has become even more crucial when we consider climate change. There will be a whole different suite of stressors. Well not necessarily different but more intensive. One insight from the recent drought that is when we think about climate change under drought conditions, we think of water scarcity. But what shows up in the data is that drought removes natural variability from a hydrograph. So as the drought continued, we were managing straight line flows.
6. How can unreliability be addressed in water supply reliability estimation? How can estimates of variability and uncertainty be improved.

Uncertainties from upstream models (hydrology, etc.) are neglected in water supply reliability estimation. Estimating uncertainties for climate change and adaptations to climate change are a challenge. A Monte Carlo approach might give a different result. Currently we rely more on historical hydrology and rely less on distributions of what could happen.

Common standards.

We definitely need better data to support the tools, and consistency of application between tools and things. Monthly models are wonderful for some applications, but we need to look at other applications from a daily basis when, especially when we're looking at various and different flow regimes and the frequency and duration of diversions into bypasses. Diversions do provide the fisheries folks and other biologists with information to help them assess the impact of diversions. Would this be beneficial or impactful?

Our model are monthly models. You hear a lot of talk about these big atmospheric rivers and short time periods where you're having a lot of runoff. Those are things that are not captured. A lot of work needs to be done to improve how the state water project captures climate change and uncertainty.

A major concern is how to best capture uncertainty in all of the inputs. We use a process called robust decision making, which is a way to get at uncertainty. For example, we know that there are a lot of different climate models and a lot of assumptions go into them. And then they are down-scaled and create uncertainty in space and how that will impact our supplies from the Colorado River, the State Water Project, and locally. Robust decision making aggregates and considers the impacts of all the components of climate change. You can separate precipitation effects, temperature effects, and expand the range of climate impact beyond the model sets that currently exist. That takes a lot of and computing power.

The way that we have approached uncertainty with robust decision making is a little bit different. You actually sort the uncertainty space by defining a range of temperature and precipitation changes. So for instance, for the Colorado river basin, we might look at a temperature increase ranging from zero to four degrees Celsius. And we would look at a precipitation change of plus or minus 20%.
Sometimes it's not appreciated how sensitive model outputs can be to subjective model inputs. The trouble is the models do well on the initial range of hydrologic conditions. They do well in a normal year. As you stress the system, such as in extreme droughts, they do not do as well. That is precisely the condition when water managers are most interested.

Reliability is a major limitation for extreme conditions. That makes a lot of sense because a model is a simplification of all operating worlds. We assume a set of operating rules that apply under most conditions.
Appendix C. Acronyms/Glossary

CALSIM – California Simulation model, DWR-USBR model of Central Valley, CVP, and SWP water supply operations and planning

CalLite – simplified CALSIM model, DWR and USBR have separate versions

CALVIN – California Value Integrated Network (UC Davis – UC Merced system optimization model)

CCWD – Contra Costa Water District

CEFF – California Environmental Flows Framework

CRSS – Colorado River Simulation System (USBR)

CVP – Central Valley Project (federal)

DCO – Delta Coordinated Operations

DSM2 – Delta Simulation Model 2 – DWR hydrodynamics and water quality model of the Delta

DWR – Department of Water Resources, California

EBMUD – East Bay Municipal Utility District

EDF – Environmental Defense Fund

IRPSIM – Integrated Regional Planning Simulation (MWDSC model)

LCPSIM – Least-Cost Planning Simulation (DWR model of urban water service area economics and decisions)

MWDOC – Municipal Water District of Orange County

MWDSC – Metropolitan Water District of Southern California

MWQI – Municipal Water Quality Investigations (DWR program)

SacWAM – SWRCB simulation model for Sacramento Valley and Delta

SCVWD – Santa Clara Valley Water District

SDCWA – San Diego Country Water Authority

SFPUC – San Francisco Public Utility Commission

SGMA – Sustainable Groundwater Management Act, California’s 2014 legislation on groundwater overdraft
